Analysis of the elemental content of a sample by irradiation with neutrons and measurement of the induced radioactivity are described.

1 INTRODUCTION

Chemical analysis by nuclear activation is an elemental analysis, i.e. it determines the contents of the various elements in the analyte sample, but cannot tell in what chemical form (compounds, valence states, etc.) they are present. The analysis is based on a reaction of the analyte element with nuclear projectiles (neutrons, accelerated small charged particles, e.g. protons, or γ-photons) [Equation 1]:

\[ \text{target + projectile} \rightarrow \text{light product + heavy product} \]

(1)

In instrumental neutron activation analysis (INAA) the projectile is a thermal neutron and the measurement of the concentration of the element is done via the heavy product, if it is a radionuclide which emits γ-rays. The amount produced of the radionuclide is proportional to the number of the target atoms.

2 BASIC NUCLEAR PHYSICS

This section gives only a brief description of basic knowledge. Readers who are interested in further detail should consult common textbooks.1–6

2.1 Radioactive Decay

Most radioactive decays occur via the transformations neutron → proton and proton → neutron and are called β-decays. They are characterized by the mass number, \( A \), which remains unchanged, whereas the atomic number is changed by ±1. There are three transformations of this type. A neutron is transformed into a proton by a β− process [Equation 2]:

\[ n \rightarrow p^+ + \beta^- + \bar{\nu} \]

(2)

The proton remains in the nucleus, whereas the electron (\( \beta^- \)) and the antineutrino (\( \bar{\nu} \)) are emitted from the nucleus, with high kinetic energies. The electron is written as \( \beta^- \) and not \( e^- \), to show that it is not an atomic electron. A proton can be transformed into a neutron by two processes. One process is \( \beta^- \) decay, in which a proton is transformed into a neutron and a positron (\( \beta^+ = e^+ \)), an entity similar in mass to an electron but which has an opposite charge [Equation 3]:

\[ p^+ \rightarrow n + \beta^+ + \nu \]

(3)
In this process there is also an emission of a neutrino (ν). Another process is the reaction of a proton with one of the surrounding electrons in the atom to yield a neutron. This process is called electron capture (EC). The neutrino and antineutrino are very small particles with no charge, and consequently they are very difficult to detect. They are not important in activation analysis, except for their effect on the β energies, which will be explained later.

Most radionuclides are not pure β emitters, but they emit simultaneously also a γ-photon (more accurately, the γ emission occurs in a very short time of <10^{-10} s after the β emission). γ-Rays are electromagnetic waves, like light and radio waves, but they have much higher energies (much shorter wavelengths). They have usually higher energies than X-rays, although the main difference between X-rays and γ-rays is their sources. X-rays are due to atomic transitions (transitions between different energy levels of electrons), whereas γ-rays are due to nuclear transitions (transitions between different energy levels of the nucleons). In most cases β^- decay does not yield the ground state of the product nuclide, but forms it in an excited state. The excited-state nuclide decays very rapidly (in most cases) to the ground state by the emission of either γ-rays or atomic electrons called conversion electrons. The emitted conversion electrons have no importance in activation analysis and we can neglect their emission and refer only to the emission of γ-rays.

A very important difference between β processes and γ decay (besides the difference in entities of the emitted particles, electrons vs photons, and the difference in ΔA, ±1 in the β process and 0 in the γ decay) is the fact that in β processes there is emission of two particles, β^- and ν or β^+ and ν, whereas in γ decay there is emission of only one photon. There are cases of the emission of a few photons from the same nuclide, but these are successive emissions and not a simultaneous emission as in the β processes. The importance of this difference lies in the fact that each nuclear decay is a transformation between two discrete energy states, resulting in a definite energy released in the process. If only one particle is emitted from the nucleus, this particle has a defined energy. When two particles are emitted, the released energy is distributed between them, and each particle can have a spectrum of energies ranging from zero up to a maximum energy, equal to the released energy. Since the emitted γ-rays have definite energies, they can be used in order to identify their emitters, by the measurement of the energy of the photons. As β^-particles do not have definite energies, they usually cannot be used to identify their emitters.

In INAA, we need to identify the different radionuclides (in order to know the nuclide from which they were formed), in addition to the measurement of their activities. This is the reason why INAA employs almost exclusively the measurement of the spectrum of emitted γ-rays. In a few cases, where the indicator radionuclide (IRN) is a pure β^- emitter, it can be measured only in cases where there are only few (2–3) nonspecific γ-emitter IRNs in the sample with different half-lives. Their separate activities can be measured by measuring the activities at different times (measuring the decay curve) and extracting the various activities from the time dependence of the measured activity.

We said that the γ-rays emitted are due to the de-excitation of the nuclide produced in the β process. However, this de-excitation does not always have to be by only one photon. Moreover, not all β decays lead to the same level of excitation. These two facts together with the de-excitation by emission of conversion electrons (mainly from low-lying levels) lead to the possibilities that one radionuclide can have more than one kind (energy) of photon and that the number of photons should not be equal to the number of nuclides which have decayed (disintegrated). The number of photons of specific energy emitted per 100 disintegrated nuclides is called the intensity of the γ line, expressed as a percentage. Let us consider different cases of γ line intensity in four examples of radionuclides.

1. 28Al decays completely to the 1.778 MeV excited state of 28Si. This level decays to the ground state by only one photon. This means that 28Al has only one γ line of 1.778 MeV with an intensity of 100%. This can be expressed by a diagram (called a decay scheme) of decreasing energies as shown in Scheme 1.

![Scheme 1](image)

2. 24Na decays almost completely (>99.8%) to one level of 24Mg (Scheme 2). However, this level decays to the ground state only by two successive photons. The first photon of 2.75 MeV is followed by a second photon of 1.39 MeV. This decay scheme explains why 24Na has two γ lines of 2.75 and 1.39 MeV, each with almost 100% intensity.

3. 27Mg decays to two different excited levels, resulting in two β^- with different energies, 1.59 MeV (31%) and 1.75 MeV (69%) (Scheme 3). The higher excited level (1.01 MeV) decays only 98% directly to the
4. $^{38}$Cl decays directly to three different states of $^{38}$Ar, both to two excited states of $^{38}$Ar and to the ground state of $^{38}$Ar (Scheme 4). This is the reason for $^{38}$Cl having three different energy $\beta^-$ particles (remember, it is only maximum energy, since $\beta^-$ leads to a spectrum of $\beta^-$ energies, up to $E_{\text{maximum}}$, 4.81 MeV (53%), 2.77 MeV (9%) and 1.77 MeV (38%). The higher excited state (3.77 MeV) decays almost completely to the lower excited state and only very little (0.06% of the 38%) decays directly to the ground state.

Consequently $^{38}$Cl has three $\gamma$ lines, 3.77 MeV (0.03%), 2.10 MeV (38%) and 1.60 MeV (38% + 53% = 91%). These data together with more physical data on the nuclides can be found in books collecting all the decay schemes of the nuclides,$^7$ but for application of radionuclides it is sufficient to use the collection of all the $\gamma$ lines of the radionuclides without the detailed decay scheme.$^8-10$ These collections are for all known radionuclides, but for most cases in activation analysis it is better to use a smaller collection of radionuclides, only of those potentially formed by the specific kind of activation analysis.$^{11-13}$

2.2 Kinetics of Decay of Radioactive Nuclides

The decay of radioactive nuclides is a statistical process. Thus, the number of atoms decaying per unit time (rate of decay) is proportional to the number of atoms of that specific radionuclide present in the sample. If the number of nuclei (atoms) of a specific radionuclide at time $t$ is $N^*$, their rate of disappearance (decay or disintegration) is given by Equation (4):

$$\frac{dN^*}{dt} = \lambda N^*$$

The constant $\lambda$, which is different for each radionuclide, is called the decay constant of this radionuclide. Integration of Equation (4) leads to the decay equation of radionuclides, i.e. the equation describing the time dependence of the number of atoms of the specific radionuclide [Equation 5]:

$$N^*(t) = N^*_0 e^{-\lambda t}$$

where $N^*_0$ is the number of atoms at time chosen as $t = 0$. Equation (5), which is the same as the integrated equation of any first-order chemical process, indicates the existence of a constant lifetime for the half of the atoms, which is called the half-life. It means that independently of the value of $N^*_0$, it takes the same time (for a specific radionuclide) for disintegration of half of the atoms, leaving only $N^*_0/2$ atoms of that radionuclide. Substituting $N^*(t)$ by $N^*_0/2$ in Equation (5) leads to the correlation between the half-life ($t_{1/2}$) and the decay constant ($\lambda$) [Equation 6]:

$$t_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.693}{\lambda}$$

Equation (5), the decay equation, can be written also with $t_{1/2}$ instead of $\lambda$ [Equation 7]:

$$N^*(t) = N^*_0 (0.5)^{t/t_{1/2}}$$

The advantage of Equation (7) over Equation (5) is in that it gives a better ‘feeling’ for the extent of the decay. Thus, for example, if the half-life is $t_{1/2} = 2.5$ days, we know that after 2.5 days only half of the original atoms remain, and after 5 days the number of original atoms is reduced to one quarter. Equation (5) was easier to use when people were using tables of exponents. Nowadays
with computers there is no difference which equation is used. In tables of data, only \( t_{1/2} \), the half-life, is given. In order to use Equation (5), \( \lambda \) should be calculated from Equation (6).

### 2.3 Kinetics of Chain Decays

In some cases a radionuclide decays not to a stable nuclide but to another radionuclide setting a chain of decays. Each chain is terminated in a stable nuclide. For a chain of decays as shown in Equation (8):

\[
R_1 \rightarrow R_2 \rightarrow R_3 \rightarrow \ldots \rightarrow R_n \rightarrow S
\]

where \( R \) denotes a radionuclide and \( S \) stands for a stable isotope, the number of atoms \( R_k \) at time \( t \) assuming that at time zero only \( R_1 \neq 0 \) and is equal to \( R_0^1 \) is given by the Bateman equation [Equations 9 and 10]:

\[
R_n = C_1 e^{-\lambda_1 t} + C_2 e^{-\lambda_2 t} + \ldots + C_n e^{-\lambda_n t}
\]

(9)

\[
R_n = \sum_{i=1}^{n} C_i e^{-\lambda_i t}
\]

(10)

where [Equations 11 and 12]:

\[
C_1 = \frac{\lambda_1 \lambda_2 \lambda_3 \ldots \lambda_{n-1} N_1^{0}}{(\lambda_2 - \lambda_1)(\lambda_3 - \lambda_1)\ldots(\lambda_n - \lambda_1)}
\]

(11)

\[
C_2 = \frac{\lambda_1 \lambda_2 \lambda_3 \ldots \lambda_{n-1} N_1^{0}}{(\lambda_1 - \lambda_2)(\lambda_3 - \lambda_2)\ldots(\lambda_n - \lambda_2)}
\]

(12)

and generally [Equation 13]:

\[
C_k = \frac{\sum_{i=1}^{n} N_1^{0}}{(\lambda_i - \lambda_k)}
\]

(13)

This is the solution of \( n \) simultaneous differential equations [Equations 14 and 15]:

\[
\frac{dR_1}{dt} = -\lambda_1 R_1
\]

(14)

\[
\frac{dR_k}{dt} = \lambda_{k-1} R_{k-1} - \lambda_k R_k \quad (k = 2, 3, \ldots, n)
\]

(15)

### 2.4 Kinetics of Formation of Radioactive Nuclides by Irradiation

When a thin target is bombarded with a beam of projectiles, the rate of nuclear transformation (the number of nuclides produced per unit time) is proportional to the beam intensity (\( I \) = number of incident particles per unit time), to the target nucleus density (\( n \) = number of target nuclei per unit volume) and to the thickness of the target (\( dx \)). The proportionality to the thickness of the target is limited to sufficiently small \( dx \), such that both the intensity of the beam and the energy of the projectiles remain practically unchanged. The proportionality constant is denoted \( \sigma \) and is called the reaction cross-section. This term comes from a simple model, assuming that each geometrical collision leads to a nuclear reaction. In this case, \( \sigma \) is the geometrical cross-section of the collision pair, \( p(r_1 + r_2)^2 \) [Equation 16]:

\[
\frac{dN^*}{dt} = \sigma \ln dx
\]

(16)

Since the nucleus radius is a few femtometers (10\(^{-13}\) cm), the cross-sections are of the order of 10\(^{-24}\) cm\(^2\). This is the reason why it has been customary to express cross-sections in units of barns, where 1 barn (b) = 10\(^{-24}\) cm\(^2\).

Equation (16) assumes that the beam cross-section is smaller than the target size facing the beam, and consequently each projectile particle is transversing through the target. In the case that the target size is smaller than the beam cross-section, the beam intensity, \( I \), should be replaced by the product \( \phi A \), where \( \phi \) is the beam flux (number of projectile particles per unit area and per unit time) and \( A \) is the area of the target facing the beam [Equation 17]:

\[
\frac{dN^*}{dt} = \phi \sigma A \ln dx
\]

(17)

\( A \ dx \) is the volume of the target and consequently \( nA \ dx \) is the total number of target atoms, \( N \) [Equation 18]:

\[
\frac{dN^*}{dt} = \sigma \phi N
\]

(18)

Since we are speaking of a reaction of a specific nuclide, \( N \) is the total number of the atoms of that nuclide. Equation (18) is used mainly for irradiation in a nuclear reactor, where the target is located inside a uniform flux of neutrons. Equation (10) is used in cases of a narrow beam from charged particle accelerators.

In the case of prompt activation analysis, the only important number is the number of nuclei which were transformed by the nuclear reaction. Hence the number of nuclei transformed is given by the integration of Equation (16) or (18) over the irradiation time. However, for delayed activation analysis, the important factor is the number of nuclei decaying during the measurement period, which is delayed and done some time after the end of irradiation. In calculating the number of nuclei of the newly formed radionuclide at the end of the irradiation, it would be wrong to integrate those equations. The radionuclides are not only formed during the irradiation, but also are decaying. Combining Equations (18) and (4) leads to the complete equation for the rate of the change
of the number of radioactive nuclei during the irradiation in a constant flux of projectiles ($\phi$) [Equation (19)]:

$$\frac{dN}{dt} = \alpha \phi N - \lambda N^*$$  \hspace{1cm} (19)

Integration of Equation (19) with the initial condition $N^*_0 = 0$ leads to the equation for the number of radioactive nuclei at the end of irradiation for time $t_i$ [Equation (20)]:

$$N^*_{EOI} = \frac{\alpha \phi N}{\lambda} (1 - e^{-\lambda t_i})$$  \hspace{1cm} (20)

where $t_i$ is the irradiation time and EOI stands for end of irradiation. In the product $\lambda t_i$, $\lambda$ should have the same units as $t_i$ whereas in the term before the parentheses the units should be the same as the time unit of $\phi$.

For cases where $\lambda t_i \ll 1$ ($t_i \ll t_i/\lambda$, the term in parentheses is approximately equal to $1 - \lambda t_i$ for $\lambda t_i \ll 1$ and $N^*_{EOI}$ is equal to $\alpha \phi N t_i$, i.e. the rate of formation multiplied by the irradiation time, since the decay is negligible.

For an irradiation time that is long relative to the half-life of decay ($t_i > t_i/\lambda$, $t_i \gg 1$), the term in parentheses is equal to 1, which is its maximum value. This is the maximum number of nuclei which can be formed. Longer irradiation does not increase the number of radioactive nuclei, since the rate of formation by the nuclear reaction is equal to the rate of disappearance by radioactive decay. This statement assumes that $N$ does not change substantially during the irradiation, which is common for the usual values of $\phi$ ($10^{15}$ n s$^{-1}$ cm$^{-2}$), $\lambda$ (1 b) and $t_i$ (<10 days). For the extreme cases $\Delta N/N$ is still usually $\leq 10^{-3}$. This maximum number of radionuclides formed is termed the saturation value or the number at saturation, $N^*_{sat}$ [Equation (21)]:

$$N^*_{sat} = \frac{\sigma \phi N}{\lambda}$$  \hspace{1cm} (21)

The saturation value can be increased by increasing the flux of the bombarding particles or the amount of the irradiated nuclei (the mass of the target), but not by longer irradiation. Usually we speak of the mass of a specific element in the target and not of the number of atoms of this element, so it is desirable to transform $N$, the number of atoms, into $m$, the mass of specific element in the activated samples. The number of atoms $N$ in $m$ mg of element with atomic weight $M$ is $(m/M)N_A$, where $N_A$ is Avogadro’s number. In contrast to the usual chemical measurements, where all natural isotopes of the same element react in almost the same way, this is not true for nuclear activation. For example, let us consider chlorine. Chlorine has two stable natural isotopes, $^{35}$Cl with 75.77% abundance and $^{37}$Cl with 24.23% abundance. Irradiation with thermal neutrons leads to an ($n,\gamma$) reaction forming the two radionuclides, $^{36}$Cl and $^{38}$Cl. $^{36}$Cl cannot be used as IRN for activation analysis owing to absence of $\gamma$ radiation ($^{36}$Cl is a pure $\beta$ emitter) and its long half-life (the IRN is a radionuclide used for the identification and quantification of an element in activation analysis). Hence, it is not the total number of chlorine atoms that should be used in Equations (18–21) but rather the number of $^{37}$Cl atoms alone. This is done by multiplying $N$ by the abundance of the parent of the IRN (0.2423 for $^{37}$Cl). Using $f$ for the abundance, Equation (21) takes the form of Equation (22):

$$N^*_{sat} = \frac{m}{M} N_A f \frac{\sigma \phi N}{\lambda}$$  \hspace{1cm} (22)

The number of the nuclei of the IRN at the end of irradiation is obtained from Equation (16) as Equation (23):

$$N^*_{EOI} = N^*_{sat}(1 - e^{-\lambda t_i})$$  \hspace{1cm} (23)

The measurement of the $\gamma$ activity (the rate that the $\gamma$-rays are emitted by the activated sample) is done not immediately after the end of irradiation, but rather after some time, which is called the decay time, $t_d$. The decay time (called also ‘cooling’ time) can be fairly short, being only the time required to transfer the sample from the irradiation port to the measurement station, or can be long. Long decay times are used when we are interested in IRNs with medium to long half-lives (they are also called medium- to long-lived IRNs). The high activity of the short-lived radionuclides at short times after irradiation obscures the activity of the longer lived radionuclides. Consequently, in order to measure medium- and long-lived IRNs, their measurement is delayed. This is the reason why the decay time is called also ‘cooling time’. For determining the concentrations of many elements in the sample, the $\gamma$ activity in the irradiated sample is measured several times (at least three) after different decay times. Since the number of atoms of the IRN at the beginning of the decay time is $N^*_{EOI}$, the number at the end of the decay period, $t_d$, is given by Equation (24) [according to Equation (5)]:

$$N^*_{EOD} = N^*_{SOC} = N^*_{EOI}e^{-\lambda t_d} = N^*_{sat}(1 - e^{-\lambda t_i})e^{-\lambda t_d}$$  \hspace{1cm} (24)

The subscripts EOD and SOC stand for end of decay and start of counting, respectively. The measurement of the $\gamma$ activity is called counting, since it is done by the counting of the pulses formed in the $\gamma$-ray detection systems, due to the interaction of the $\gamma$-photons with the detector.

The counting is done during a time $t_c$ called the counting time. The number of atoms of the radionuclides still undecayed at the end of the counting time, $N^*_{SOC}$, is given by Equation (25) [according to Equation (5)]:

$$N^*_{EOC} = N^*_{SOC} e^{-\lambda t_c} = N^*_{sat}(1 - e^{-\lambda t_i})e^{-\lambda t_d}$$  \hspace{1cm} (25)
The number of atoms decaying in the counting period \( \Delta N_c \) is given by the difference in the number of atoms at the beginning of the counting period, \( N_{SOC}^* \), and the number of atoms at the end of this period, \( N_{EOC}^* \) [Equation (26)]:

\[
\Delta N_c = N_{SOC}^* - N_{EOC}^* = N_{sat}^*(1 - e^{-\lambda t})e^{-\lambda t}(1 - e^{-\lambda t})
\]  

(26)

The actual number of events of decay recorded by the detection system, is smaller than \( \Delta N_c \), owing to three different factors: (i) the intensity of the specific \( \gamma \) line (number of photons emitted per 100 atoms decayed) is in many cases < 100%; (ii) not every \( \gamma \)-photon emitted reaches the detector, as the photons are emitted isotropically and only those in the direction of the detector will hit the detector; and (iii) some of the photons reaching the detector will not interact with it, and others will lose only part of their energy in the detector, and consequently will not be recognized as originating from the specific IRN. The last two factors are combined in a factor called the geometric efficiency of the detector, \( \varepsilon \). This factor depends on the detector, the energy of the \( \gamma \) line and the distance of the sample from the detector. For large samples, \( \varepsilon \) depends also on the sample size. The factor \( \varepsilon \) is determined experimentally by counting the activity of calibrated standards (which can be bought commercially), for which the rate of disintegration is known accurately. The rate of decay of the standards is given on its certificate at specific date and time. Its activity at the time of calibrating of the standards is given on its certificate at specific date and time. Its activity at the time of calibrating of the standards is given on its certificate at specific date and time. Its activity at the time of calibrating of the standards is given on its certificate at specific date and time.

\[
C = \varepsilon I_g \Delta N_c
\]

(27)

where \( I_g \) is the intensity of the specific \( \gamma \) line. Thus, for activation in a uniform flux, the number of measured counts is given by Equation (28):

\[
C = mN_A f \sigma \phi I_g \frac{1 - e^{-\lambda t}}{\lambda} e^{-\lambda t}(1 - e^{-\lambda t})
\]  

(28)

For a beam smaller than the target, \( \phi \) is replaced by \( I/A \), where \( A \) is the area of the target, usually expressed by \( n_{sample} / (\rho \ dx) \). It should be noted that here the mass is the total mass of the sample and not the mass of the determined element; \( \rho \ dx \) is the common way in nuclear physics to express thickness and its units are grams per square centimeter.

Equation (28) shows that the number of counts recorded is proportional to the mass of the element responsible for the specific \( \gamma \) line, and this is the basis of the activation method since the measurement of the specific \( \gamma \) line yields the mass in the sample of the specific original nuclide.

For some elements, mainly gold and tantalum, the radionuclides produced by the \((n,\gamma)\) reaction with the reactor neutrons have exceptionally high cross-sections (e.g. for \(^{198}\text{Au}\) the cross-section is \(2.5 \times 10^4\) b). Owing to the high cross-section and although their concentration is very limited, a radionuclide is formed by absorption of two neutrons (in two consecutive steps and not in one interaction) in the stable nuclide. For example, for gold, which has only one stable isotope, \(^{197}\text{Au}\), the process is illustrated by Equation (29):

\[
^{197}\text{Au} \longrightarrow ^{198}\text{Au} \longrightarrow ^{199}\text{Au}
\]  

(29)

\[
^{198}\text{Hg(stable)} \longrightarrow ^{199}\text{Hg(stable)}
\]

For \(^{198}\text{Au}\), the rate of formation is given by Equation (30):

\[
\frac{d[^{198}\text{Au}]}{dr} = [^{197}\text{Au}]\sigma_1 \phi - (\lambda_1 + \sigma_2 \phi)^{[^{198}\text{Au}]}
\]  

(30)

Equation (30) is the same as Equation (19) substituting \( \lambda \) for \( \lambda_1 + \sigma_2 \phi \). Hence the number of \(^{198}\text{Au}\) atoms at the end of irradiation is given by Equation (31):

\[
N^{(198}\text{Au})_{EOI} = \frac{\sigma_1 \phi [^{197}\text{Au}]}{\lambda_1 + \sigma_2 \phi} [1 - e^{-(\lambda_1 + \sigma_2 \phi)t}]
\]

\[
= \frac{\sigma_1 \phi [^{197}\text{Au}]}{\lambda_1} [1 - e^{-\sigma_1 t}]
\]  

(31)

For \(^{199}\text{Au}\), the rate of formation is given by Equation (32):

\[
\frac{d[^{199}\text{Au}]}{dr} = \sigma_2 \phi [^{198}\text{Au}] - \lambda_2 [^{199}\text{Au}]
\]  

(32)

This is similar to the set of the differential Equations (15), differing in that the constants in the positive term in one equation differ from those in the negative term in the next one, as not all of the disappearance of \( R_i \) leads to \( R_{i+1} \); however the same method of Bateman can be used also here. The solution of Equation (32), substituting in it Equation (31), yields Equation (33):

\[
[^{199}\text{Au}] = \frac{\sigma_1 \sigma_2 \phi^2 [^{197}\text{Au}]^0}{\alpha_1 \lambda_2} \left(1 - \frac{\lambda_2 e^{-\alpha_1 t} - \alpha_1 e^{-\lambda_2 t}}{\lambda_2 - \alpha_1}\right)
\]  

(33)

This equation neglects the disappearance of \(^{199}\text{Au}\) due to the absorption of neutrons. An equation which includes it was given by Heydorn,\(^{14}\) but its contribution is negligible for all fluxes used in activation analysis. The general treatment can be found in Friedlander et al.,\(^{3}\) (p. 201).
3 THE SHAPE OF A $\gamma$ SPECTRUM

In optical (absorption and emission) spectrometry we know that if a species has only one excited state its spectrum will appear as a single line without any background. This is due to the yes/no quantum characteristic of the energy transfer. The energy difference between the two states is either transferred or not transferred, but it cannot be transferred in parts. A photon of light in the infrared, visible or ultraviolet range can be absorbed totally or not at all, but it cannot lose only part of its energy. The situation is different for high-energy $\gamma$-rays. Low-energy X-rays interact with matter by the photoelectric process. In this process the $\gamma$-photon interacts with one electron of the material, losing all its energy to this electron. The transferred energy is higher than the binding energy of the electron, and thus the electron is ejected from the atom with kinetic energy equal to this difference ($h\nu_{\text{photon}}$ = binding energy of the electron). However, since the range of high kinetic energy electrons is considerably shorter than that of $\gamma$-rays, the electrons will lose their kinetic energy inside the detector material and from the point of view of the detector the complete energy of the photon have been absorbed in it, resulting in the same energy absorbed for all photons (assuming that all photons are of the same energy). The situation is different for higher energy $\gamma$-rays. The cross-section (probability of reaction = rate constant) for the photoelectric process decreases with increasing energy of the photon more than that of the Compton scattering. For higher energy photons the main interaction with matter is via Compton scattering. In germanium the photoelectric effect is the dominant process for $\gamma$-ray interaction up to about 200 keV, whereas from 200 keV upwards the Compton scattering becomes more important. It should be stressed that also below 200 keV the Compton scattering occurs but its contribution to the interaction of the photon with the germanium is less than that of the photoelectric process. Its contribution increases with the energy although its cross-section decreases with the energy, since it decreases less than that of the photoelectric process. In the Compton scattering the photon interacts with what might be called a free electron (mainly electrons from outer shells whereas the photoelectric process occurs with inner shell electrons, mainly from the innermost one, the K shell). The photon transmits only part of its energy. The energy that the electron receives is more than sufficient to eject it from the atom and it moves with the excess energy as kinetic energy, losing it by collisions in a very short distance. The photon retains part of its energy, by changing its frequency since $E = h\nu$, and scattered in a different direction. In the Compton process the energy of the original photon is shared between two particles (the ejected electron and the scattered photon), and consequently there is a continuous distribution of energies of the scattered photon. In order to conserve both energy and momentum, the $\gamma$-photon cannot lose all its energy (in the photoelectric effect the momentum conservation is compensated by the recoiling of the atom from which the electron was ejected, whereas in Compton scattering it is an interaction with a ‘free’ electron). The maximum energy that the photon can lose is given by Equation (34):

$$E_y \frac{1}{1 + m_0c^2/2E_y}$$

where $E_y$ is the energy of the initial photon and $m_0$ is the electron rest mass; $m_0c^2$ is the rest mass of an electron in energy units and it is equal to 0.511 MeV. The main difference between the photoelectric and Compton processes with respect to their responses in the detector material is that the electrons (in both processes) lose all their energy in the detector, owing to their short range, while the scattered photon might escape from the crystal without further interaction. In $\gamma$-ray spectrometry we are measuring the full-energy peak, called the photopeak, as this energy will be the only one to appear if the only interaction process is photoelectric absorption. The photopeak results either from the $\gamma$-photons losing all their energy by photoelectric absorption or from a Compton scattering process followed by photoelectric absorption of the scattered lower energy $\gamma$-photon in the detector (the photoelectric absorption can be after one scattering or several scatterings, all of them within the detector material). However, the scattered $\gamma$-photon from the Compton process (actually from the several consecutive Compton processes) might escape from the detector crystal, leaving in the detector less energy than the full energy peak. This escape of scattered photons not only reduces the photopeak, but its main disadvantage is the formation of a background for lower energy peaks, since part of the energy (those given to the electron) is absorbed in the detector and the detector sees them as counts of lower $\gamma$ energy than the actual energy of the $\gamma$-photon emitted by the IRN. The scattered photons do not have discrete energy and can be between a minimum given by Equation (34) and a maximum given by the original energy of the photon (minus the small value of the binding energy of the photon, which is not completely a free electron). For one $\gamma$ energy source the Compton scattering produces a continuum background ranging from zero up to a maximum, called the Compton edge, given by Equation (35). This results from the fact that the minimum energy that the scattered photon can have is not zero but rather is given by Equation (35):

$$E_{\text{minimum of scattered } \gamma} = E_y - \frac{E_y}{1 + m_0c^2/2E_y} = \frac{E_y m_0c^2}{2E_y + m_0c^2}$$
For $E_\gamma \gg m_0c^2$, $E_{\text{minimum}}$ approaches a value of $m_0c^2/2$, i.e. 256 keV. Thus, for high-energy $\gamma$ the Compton edge will be separated from the photopeak by about 256 keV. For a one-energy source the range between the photopeak and the Compton edge is almost free of counts. However, most real samples have many IRNs having different $\gamma$ energies and the Compton continuum stretches from zero up to the Compton edge of the highest $\gamma$ energy.

If the energy of the measured photon is $> 1.022$ MeV, a third process can also be operative in the interaction of the photon with the detector—a process called pair production. In this process, the photon energy is transformed, under the influence of the field of a nucleus, into matter in the form of an electron–positron pair (transformation of energy into a matter–antimatter pair). Since the rest mass of each electron or positron is $0.511$ MeV, the threshold of this reaction is $1.022$ MeV to conserve energy. Although the threshold energy is $1.022$ MeV, the cross-section for pair production is very low, for the energy range of $< 1.5-1.6$ MeV, and can be ignored. In this process of pair production, the excess energy of the electron and the positron. Since the ranges of excess energy is shared between the kinetic energies be ignored. In this process of pair production, the photon energy of the photon with the detector – a process called pair production. In this process, the photon energy is transformed, under the influence of the field of a nucleus, into matter in the form of an electron–positron pair (transformation of energy into a matter–antimatter pair). Since the rest mass of each electron or positron is $0.511$ MeV, the threshold of this reaction is $1.022$ MeV to conserve energy. Although the threshold energy is $1.022$ MeV, the cross-section for pair production is very low, for the energy range of $< 1.5-1.6$ MeV, and can be ignored. In this process of pair production, the excess energy is shared between the kinetic energies of the electron and the positron. Since the ranges of positrons and electrons are very short, this excess energy ($E_\gamma – 1.022$ MeV) will be deposited in the detector. When the positron has lost all its kinetic energy, it reacts with an electron in an annihilation reaction to form two $\gamma$-photons of $0.511$ MeV each (transformation of matter–antimatter into electromagnetic energy). Each of these $511$-keV photons can either escape from the detector without any interaction, or lose part of its energy by Compton scattering, or lose all its energy in the detector (either by photoelectric absorption or by successive Compton scatterings and photoelectric absorption). If one of the $511$-keV photons deposits all its energy in the detector, while the other one totally escapes from the detector, the energy absorbed in the detector will be $511$ keV less than the full energy peak. With $\gamma$-photons of above $1.6$ MeV we usually see also this peak of $E_\gamma – 511$ keV, where $E_\gamma$ is the photopeak energy. This peak is called single-escape (SE) peak, due to one $511$-keV photon escaping from the detector. Another peak in the spectrum is the double-escape (DE) peak, rising from the two $511$-keV photons escaping from the detector without any interaction with the detector material. The energy of this peak is $E_\gamma – 1.022$ MeV. When analyzing a $\gamma$-ray spectrum to find the radionuclides in the analyzed spectrum, every time we find a peak with energy $E_\gamma > 1.6$ MeV, which we know belongs to some radionuclide, we have to remember that in the list of the found peaks there are some which do not belong to other radionuclides but are either SE or DE peaks. We saw that $^{28}$Al has a $\gamma$ energy of 1.778 MeV. Hence we expect to see in the $^{28}$Al $\gamma$-ray spectrum peaks of 1.778 MeV, 1.269 MeV (SE = 1.778 – 0.511) and 0.758 MeV (DE peak). $^{24}$Na has two $\gamma$ lines of 2.75 and 1.39 MeV. We expect to have four lines in the $\gamma$-ray spectrum, 2.75 MeV, 2.24 MeV (SE), 1.73 MeV (DE) and 1.39 MeV. Although 1.39 MeV is above the threshold of 1.022 MeV for pair production, its cross-section for this process is low and pair production contributes very little to the interaction of the 1.39 MeV photon with the detector. Hence in most cases we will not see the SE and DE peaks of this photon.

Figure 1 shows the measured $\gamma$-ray spectrum of $^{24}$Na. The ratio of escape peaks to the photopeak depends on the detector size (influencing the probability of the $\gamma$ escape) and on the energy of the $\gamma$-photon (affecting the chance that the photon will interact by pair production). In order to know whether a peak is a photopeak or SE or DE, it is preferable to start the analysis of the spectrum from the highest energy peak. For each peak we can remove from the list of peaks its SE and DE peaks.

An important artefact in many $\gamma$-ray spectra is the sum peak, a peak which is due to the summation of two $\gamma$-photons. If two photons are interacting with the detector, and the time between them reaching the crystal is smaller than a time characteristic of the detector, the detector treats both of them as a single photon and the energy deposited is the sum of the energies of the two photons. The two photons can be due to different radionuclides,
or to the same radionuclide which has more than one γ line. In the case of different radionuclides the sum peak is refer to ‘pile-up’ and can be reduced (relative to the photopeaks) by removing the measured sample further from the detector or by analyzing a smaller sample. A lower rate of counting increases the average time between two photons reaching the detector, thus decreasing the chances of pile-up. In the spectrum of only one γ line there is also a peak with energy given by Equation (35). This peak is due to 180° backscattering from external sources, mainly the shielding of the detector, of the original photon. The backscattered Compton photon reacts with the detector, giving a peak of its full energy. For a source with various γ-ray energies, this backscatter peak can range from 70 to 256 keV, thus adding to the Compton continuum rather than forming a distinct peak.

The Compton background is an intrinsic background due to the physical characteristics of the detector and the interaction of radiation with matter. Another source of background is external, due either to radioactive sources other than our sample or to cosmic radiation. This external background can be minimized by the use of shielding, done mainly with lead owing to its high Z and mainly its high density. Usually the detector is located inside a lead ‘castle’. Lead shielding configurations suitable for a germanium detector are available commercially, usually in the form of a hollow cylinder with a sliding lid or revolving door for access.

In many cases where the Compton continuum interferes with the measurements of mainly small peaks, it can be reduced by the use of the Compton suppression method. In this method, the germanium detector is located inside an annular scintillation detector or inside a ring of scintillation detectors. Many of the scattered Compton γ-rays which escape from the germanium detector (in the case of the Compton continuum) deposit some energy in the surrounding detectors, whereas those photons which lose all their energy in the germanium detector do not cause any signal in the scintillation detector(s). The system is operated in the anticoincidence mode, i.e. the multichannel analyzer (MCA) is recording only the events which occur only in the germanium detectors. If within a fixed time the pulse in the germanium detector is followed with a pulse in the scintillation detector (indicating that the germanium pulse is in the Compton continuum and not part of a photopeak), this event is discarded. The scintillation detector(s) are usually NaI(Tl), although in some systems it is a crystal of bismuth germanate (BGO) (Bi$_2$Ge$_3$O$_{12}$) owing to its higher efficiency for absorption of γ-rays (since it has a high-Z element). However, BGO crystals are more expensive and are not used in most systems. A schematic diagram of a Compton suppression system is given in Figure 2.

Figure 2 Schematic diagram of anticoincidence Compton suppression γ-spectrometer. (1) HPGe detector with liquid nitrogen cooling; (2) NaI(Tl) detectors with photomultipliers.

4 NEUTRON SOURCES

Three main sources of neutrons are available: (1) research nuclear reactors (nuclear reactors used as neutron sources), (2) ion and electron accelerators including neutron generators and (3) radioactive sources.

Research nuclear reactors have the highest neutron fluxes, but are limited concerning their price and availability. Consequently, nuclear reactors will be used for INAA of very minute amounts, which is the main subject of this article. Research nuclear reactors are usually large devices in which fissionable material, almost exclusively $^{235}$U, is fissioned into two nuclides with simultaneous emission of neutrons which induce further fissions in a chain reaction. The fission-produced neutrons are very energetic. The cross-section for neutron-induced fission of fissionable nuclides increases with decreasing energy of the neutrons, and in order to increase the neutron activity, moderators which slow the neutrons are added to the reactor. To reflect back some of the neutrons which leak from the reactor core, reflectors are used. The fission process releases large amounts of energy, mainly due to the stopping of the two recoiling fissioned particles, and the system is cooled by a coolant (either liquid or gas). Nuclear reactors are categorized according to their fuel, moderator, coolant, reflector and configuration.

Almost all research nuclear reactors (neutron sources) are heterogeneous reactors in which the fuel is in the form of rods. The fuel is enriched $^{235}$U (natural uranium has only 0.7% of $^{235}$U, the fissile material). Most research reactors have 93–99% $^{235}$U. Many of the reactors have rods which are U–Al alloys, but some
of the newer designs (mainly those converted to 20% $^{235}\text{U}$) are of the uranium silicide type. TRIGA reactors operate with uranium–zirconium hydride fuel, which, owing to their large negative temperature coefficient of reactivity, allow the operation of the reactor in pulses. In the light water reactor (LWR), ordinary water ($\text{H}_2\text{O}$) is used both as a moderator and as a coolant. The reflector is mainly graphite but there are also Be and $\text{H}_2\text{O}$ reflected reactors. The construction is either pool type or tank-in-pool type. Owing to the relative high cross-section for capturing thermal neutrons by H atoms and therefore the relatively small amount of moderator, the flux of neutrons in LWRs always contains a large fraction of fast and epithermal neutrons. The available powers are in the range 10–5000 kW with neutron fluxes of $5 \times 10^{10} – 1.5 \times 10^{14} \text{n cm}^{-2} \text{s}^{-1}$. Many reactors are unique in their design, but there are some commercial types which are more common, e.g. the American TRIGA and the Canadian Slowpoke. The TRIGA reactor is a popular multipurpose research reactor. About 50 of them are operating with power levels of 18 kW–3 MW fluxes of $7 \times 10^{11} – 3 \times 10^{13} \text{n cm}^{-2} \text{s}^{-1}$. The most common types are those of 100–250 kW and 1 MW. They are of the pool type, graphite reflected with uranium–zirconium hydride fuel with $^{235}\text{U}$ enrichment of 10–70%. The Slowpoke reactor is a low-power (20 kW) reactor designed specifically as a teaching aid for the production of small amounts of radioisotopes. The system is designed to operate remotely. It can be provided with up to five irradiation sites in the core with a flux of $10^{12} \text{n cm}^{-2} \text{s}^{-1}$ and five further tubes outside the reflector with half of that flux.

Heavy water research reactors are tank types. They contain usually enriched uranium fuel. Heavy water is used as both moderator and cooler, and neutrons are reflected from the heavy water and graphite. Owing to the low cross-section for thermal neutron absorption by D and O, and owing to the higher mass of moderator, they are characterized by a well-thermalized neutron flux (very little epithermal and fast neutron fluxes except inside the core). Owing to the lower moderation power of D compared with H, the physical size of heavy water reactors is larger and hence they have a large available irradiation volume. Their power is usually between 10 and 26 MW (fluxes of up to $2 \times 10^{13} \text{n cm}^{-2} \text{s}^{-1}$).

### 4.1 Sample Introduction

The way of introducing a sample into the neutron flux depends on the physical structure of the reactor. It is essential that the introduction of the sample will not affect the operation of the reactor. The irradiation site may be within the reactor core or outside in the moderator/reflector region. If the reactor is an open-pool type with access from above, vertical tubes or ropes can be installed to lower the samples down inside the core or close to the side. The samples are closed in sealed ampules in order not to be in contact with the water surrounding the core. The ampules are usually made of aluminum owing to its corrosion resistance and short-lived activation products. For short irradiations a polyethylene capsule can also be used. The manual loading of samples is neither quick nor reproducible in time when short irradiations are performed. In order to have quick and reproducible sample introduction, mechanical systems are used. Two types of mechanical systems are used: chain-driven racks and pneumatic devices. The latter is the most common, owing to the shorter loading and unloading time and less maintenance and failures of operation. In the pneumatic device, the sample is pushed along a tube with pressurized gas (air or nitrogen). The transfer time depends on the pressure and the distance transferred. In many systems the transit time is 1 s or less. The pneumatic device can be automated very easily. Figure 3 depicts schematically the pneumatic system.

With closed-tank reactors, the irradiation is done either by a pneumatic device or with neutron beams.

### 5 INSTRUMENTAL NEUTRON ACTIVATION ANALYSIS

#### 5.1 Techniques

INAA is one of the simplest techniques for trace element analysis. Samples are inserted into polyethylene or polypropylene cans for short irradiation or into a quartz vial which is inserted in an aluminum can for long irradiation. PVC cans or glass vials cannot be used, since they will be become very radioactive owing to the formation of $^{38}\text{Cl}$ or $^{24}\text{Na}$, respectively. For a short irradiation time each sample is ‘sent’ alone into the core. The ampules are usually made of aluminum owing to its corrosion resistance and short-lived activation products. For short irradiations a polyethylene capsule can also be used. The manual loading of samples is neither quick nor reproducible in time when short irradiations are performed. In order to have quick and reproducible sample introduction, mechanical systems are used. Two types of mechanical systems are used: chain-driven racks and pneumatic devices. The latter is the most common, owing to the shorter loading and unloading time and less maintenance and failures of operation. In the pneumatic device, the sample is pushed along a tube with pressurized gas (air or nitrogen). The transfer time depends on the pressure and the distance transferred. In many systems the transit time is 1 s or less. The pneumatic device can be automated very easily. Figure 3 depicts schematically the pneumatic system.

With closed-tank reactors, the irradiation is done either by a pneumatic device or with neutron beams.
to the reactor by means of a pneumatically operated tube – the rabbit system. For long irradiation times, many samples can be lowered into the reactor and left there for the required time. After the samples have been removed from the reactors, they are counted (this means taking a γ-ray spectrum) immediately or the γ-ray spectrum is taken after some ‘cooling’ (decay) time, to reduce the high radioactivity level due to short-lived radionuclides. Before counting, the vials are washed to remove surface contaminants. In some cases the samples are counted inside the vial, whereas in others the samples are taken out of the vial before the measurement, owing to interferences from trace elements in the vial.

5.2 Calculation

In general, the first calculation step consists of peak identification, i.e., identification of which peaks are photopeaks (discarding SE, DE and sum peaks) and identification of the radioactive species which are producing them. There are tables of γ-ray energies listed in order of increasing energies for ease of identification. Some tables give the energies of all known radionuclides whereas others give them only for radionuclides which can be formed in one form of nuclear activation, e.g., in a nuclear reactor. For better identification the tables give the half-life of the measured radionuclide, its probability of formation and other properties. For identification through half-lives. It should be remembered that SE and DE energies are not listed in most libraries (9–13) and this can lead to misidentifications. Figure 4 gives an example of γ-ray spectra measured from an activated geological sample with an HPGe system 15 min after the end of irradiation. (1) 3084 keV $^{49}$Ca; (2) 2754 keV $^{24}$Na; (3) 2573 keV SE of $^{49}$Ca; (4) 2243 keV SE of $^{24}$Na; (5) 2113 keV $^{56}$Mn; (6) 2062 keV DE of $^{49}$Ca; (7) 1811 keV $^{56}$Mn; (8) 1779 keV $^{28}$Al; (9) 1732 keV DE of $^{24}$Na; (10) 1434 keV $^{52}$V; (11) 1369 keV $^{24}$Na; (12) 1268 keV SE of $^{28}$Al; (13) 1014 keV $^{27}$Mg; (14) 846 keV $^{58}$Mn + $^{27}$Mg; (15) 757 keV DE of $^{28}$Al; (16) 511 keV β⁻ annihilation; (17) 320 keV $^{31}$Ti.

where $C_i$ is the counts in channel number $i$, and $L$ and $u$ are the lower and upper channels belonging to the peak. However, this total count value contains also the background (Compton and external), which should be subtracted. Therefore, the background is estimated by taking the average number of counts in 3–5 channels on both sides of the peak, multiplying by the number of channels in the peak [Equation 37]:

$$\text{background} = \frac{u - L + 1}{2 \times 3} \sum_{i=L-3}^{u+3} C_i + \sum_{i=u+1}^{L-1} C_i$$  \hspace{1cm} (37)

The value of 3 in this equation can be increased or decreased, but it is about the optimum value; lower numbers will increase the statistical error in the evaluation of the background, and larger numbers will increase the possibility that the following channels belong already to other peaks. The radioactive decay is not an absolute process but rather of a statistical nature, and consequently the larger the number of counts the more accurate is the result. The standard deviation of each decay count (as long as the counting time is small compared with the half-life of the measured radionuclide) is equal to the square root of the number of counts. The number of net counts is given by Equation (38):

$$N = \text{net counts} = \text{total} - \text{background} = T - B$$  \hspace{1cm} (38)

The standard deviation of the net counts, $\sigma_N$, and the relative standard deviation, $\%\sigma_N$, are given by

$$\sigma_N = \sqrt{\text{net counts}}$$  \hspace{1cm} (39)

and

$$\%\sigma_N = \frac{\sigma_N}{\text{net counts}} \times 100$$  \hspace{1cm} (40)
Equations (39) and (40):
\[ \sigma_N = \sqrt{T + B} = \sqrt{N + 2B} \]  
\[ \%\sigma_N = \frac{100 \sqrt{T + B}}{N} = \frac{100 \sqrt{N + 2B}}{N} \]  

It should be kept in mind that the rate of counting is limited both by the rate of the process in the detector (which causes 'pile-up' or a sum peak in the case of high rates of counts) and by the rate of the sorting-out of pulses by the MCA and the electronic system. During the 'busy' period of the electronic system, they cannot acquire another signal, so that each signal reaching the system during its 'busy' period will be discarded. This 'busy' period is called the dead time and the actual measurement time (live time) is smaller than the real time (measured by the clock). Most MCA systems contain a device for correction of the dead time. However, these devices are accurate only up to about 10% dead time. It is usually recommended not to measure with dead time. However, these standards are calibrated in a 4π detector, i.e. a detector which surrounds the source from all directions such that any β-particle or photon interacts with the detector. The geometry factor \( \varepsilon \) depends on the distance of the source from the detector and the energy of the \( \gamma \) line. For a fixed distance, \( \varepsilon \) is a maximum type function of the energy, the maximum being at 100–150 keV. For higher energies than the maximum, \( \log \varepsilon \) is approximately a linear function of \( \log(\text{energy}) \), although for more accurate interpolation a quadratic dependence of \( \log \varepsilon \) on \( \log(\text{energy}) \) is used. Standard sources often used for calibration are \( ^{241}\text{Am} \) (60 keV), \( ^{131}\text{Ba} \) (81, 302, 356 and 383 keV), \( ^{137}\text{Cs} \) (661 keV), \( ^{60}\text{Co} \) (1773 and 1332 keV), \( ^{22}\text{Na} \) (1275 keV) and \( ^{88}\text{Y} \) (898 and 1836 keV). These standard radioactive sources are used also for the calibration of the number of channels vs. the appropriate \( \gamma \) energy. The standard radioactive sources are supplied with a certificate, certifying their activity at a fixed date. The activity is given either in microcuries [1 μCi = 3.7 × 10^6 disintegrations per second] or in kilobecquerels (1 kBq = 10^3 Bq, 1 Bq = 1 dps, 1 μCi = 37 kBq). The activity of the source at the measurement is calculated by the use of Equation (41) which is derived from Equation (2):

\[ A(t) = A_0 \exp(-\lambda t) \]  

where \( A(t) \) is the activity at the measurement time, \( A_0 \) is the certified activity and \( t \) is the time elapsed from the date of certification to the measurement.

The parameters \( f, I_p \) and \( \lambda \) are tabulated and known very accurately. However, \( \sigma \) is a function of the energy of the neutrons and the real term in Equation (28) should not be \( \sigma \phi \) but rather the integral \( \int_0^\infty \sigma(E)n(E)\,dE \), where \( n(E) \) is the energy – flux density or the flux distribution function (number of neutrons per second per square centimeter for which their energy is in the range \( E + dE \to E \)), \( \phi = \int_0^\infty n(E)\,dE \). These functions \( n(E) \) and \( \sigma(E) \) are not always known and sometimes they change with time and with location in the reactor. In order to overcome this problem, the use of comparators has been applied to calculate the results of neutron activation analysis (NAA). A comparator is a standard which contains a known amount of the element to be determined in the sample. If the sample (denoted by subscript s) and the comparator (denoted by subscript c) are irradiated simultaneously and counted under the same conditions, then Equation (26) gives Equation (42):

\[ m_s = m_c \frac{C_c D_c M_c}{C_s D_s M_s} \]  

where \( D \) is the decay factor \([D = \exp(-\lambda t_d)]\) and \( M \) is the measurement time factor \([M = 1 - \exp(-\lambda t_c)]\), where \( t_c \) is the counting time, not related to the subscript c representing the comparator. This method of comparators is the most accurate one, and it is the best one to use if the concentration of a single element (or even a few elements) in the sample is required. It should be noted that the sample and the comparators are of similar size and composition to compensate for unequal self-absorption of the measured \( \gamma \)-photons in the sample or comparator. This problem of self-absorption is almost negligible if both sample and comparators are small. The main problem in the use of a comparator for each element is when INAA is used for multielement analysis, which is the common case. In some samples more than 25 elements...
are determined simultaneously (more accurately, by three irradiations for different periods of times followed by 5–6 countings at different times after the irradiations for various periods of times).\(^{18-23}\) For these multielement determinations it is difficult to prepare comparators for all the elements, and further it become impractical owing to the large amount of space required for all the comparators. Thus for multielement analysis either multielemental comparators have to be used, or one or two element comparators are used for calculation of other elements. Some multielement standards (comparators) of different types (geological, biological, etc.) have been prepared either by groups of scientists or by governmental or international organizations. However, such a standard [standard reference material (SRM)] is not recommended as a primary standard owing to some large uncertainties in some elements and problems with homogeneity of small samples (of the SRMs) used in INAA.

The use of one or two elements as comparators for all elements has become more widely used in recent years. The advantage of using two elements or one element with two isotopes which are activated is that the use of two activated nuclides, if chosen well, can give more information on the energy distribution of the neutron flux in the reactor.\(^{24-26}\) The most popular method is the so-called \(k_0\) method, in which \(k_0\) values were determined for most of the elements according to Equation (43):

\[
k_0 = \frac{B_c}{B_s}
\]

where \([\text{Equation 44}]\)

\[
B = \frac{C}{f\sigma_{th}}
\]

and the subscripts \(c\) and \(s\) stand for comparator and sample/element, respectively, and \(\sigma_{th}\) is the cross-section for reaction with thermal neutrons. The most popular comparator is Zr, which has two activatable isotopes, used to monitor the thermal and epithermal flux simultaneously. The calculation of the amount of the different elements involves both the thermal and epithermal neutrons.

### 5.3 Nuclear Interferences

There are two main kinds of interferences in the calculation of trace element concentration by INAA. The first is the formation of the same radionuclide from two different elements. This would be almost impossible if all neutrons were thermal neutrons since then the only possible reaction is \((n,\gamma)\). However, all reactors have some higher energy neutrons, which can induce other reactions. Examples of this case are the determination of Mg in the presence of Al, Cr in the presence of Si or P. Mg can be determined only through its less abundant isotope \(^{28}\)Mg\((n,\gamma)\)\(^{27}\)Mg. The cross-section for this reaction is rather low, making this measurement not very sensitive. It suffers interference since \(^{27}\)Mg can be formed from nonthermal neutrons reacting with Al in an \((n,p)\) reaction, \(^{27}\)Al\((n,p)\)\(^{27}\)Mg. Similarly, the determination of chromium by the \(^{50}\)Cr\((n,\gamma)\)\(^{51}\)Cr reaction suffers interference from the nonthermal neutron reaction \(^{54}\)Fe\((n,\alpha)\)\(^{51}\)Cr. Al is determined by the \(^{28}\)Al\(^{27}\)Al\((n,\gamma)\)\(^{28}\)Al reaction, which can be produced also by the reactions \(^{31}\)P\((n,\alpha)\)\(^{28}\)Al and \(^{28}\)Si\((n,p)\)\(^{28}\)Al. In a flesh sample it was found that the contribution of Pt to \(^{28}\)Al is more than 10 times that of the \(^{28}\)Al from Al, in most reactors.\(^{27-31}\)

Even for only thermal neutrons in few cases a specific IRN can be formed from two elements, in cases where the IRN can be formed also by consecutive reaction with two neutrons. Pt has several IRNs but all of them except one are short-lived and suffer from interferences from the major element background. Hence, for minute amounts of Pt it is determined by \(^{199}\)Au formed in the process shown by Equation (45):

\[
{}^{198}\text{Pt} \longrightarrow {}^{199}\text{Pt} \longrightarrow {}^{199}\text{Au}(3.139 \text{ d}, 158.3 \text{ keV/line})
\]

However \(^{199}\)Au is formed also by a two-neutron reaction with \(^{197}\)Au, since \(^{198}\)Au has a very high cross-section for neutron capture \((2.65 \times 10^4 \text{ b})\)\(^{32,33}\) [Equation 46]:

\[
{}^{197}\text{Au} \longrightarrow {}^{198}\text{Au} \longrightarrow {}^{199}\text{Au}
\]

Another kind of interference is from two radionuclides having very close \(\gamma\) lines. An example of this kind of interference is the 846.8-keV line of \(^{56}\)Mn and the 843.8-keV line of \(^{27}\)Mg. Nowadays very good spectrometers are able to separate these two peaks if they have comparable activities but this is impossible for low-resolution germanium detectors or when one activity is much higher. If they cannot be separated by the spectrometer there are two ways to overcome this interference:

1. Since the half-life of \(^{56}\)Mn (2.56 h) is longer than that of \(^{27}\)Mg (9.45 min), decay of 2 h will leave practically only \(^{56}\)Mn (the activity of \(^{27}\)Mg will decrease by a factor of 6647 whereas the \(^{56}\)Mn activity will be decreased by a factor of less than two). Thus measurements of the sample after the irradiation and after decay of 2–3 h will give the activities of both \(^{56}\)Mn (from the delayed measurement) and \(^{27}\)Mg (by subtracting the corrected activity of \(^{56}\)Mn from the first measurement).

2. The activities of both radionuclides can be calculated using the fact that \(^{27}\)Mg also has another \(\gamma\) line at 1014 keV. The ratio of the activities of the two lines
can be measured in a pure sample of Mg, and thus the 843.8-keV activity of $^{27}$Mg can be calculated from the 1014-keV activity. Subtracting this activity from the combined (843.8 + 846.8)-keV peak yields the activity of $^{56}$Mn 846.8-keV peak.

### 5.4 A Test Case: Instrumental Neutron Activation Analysis of Trace Elements in Silicon

Silicon has three naturally stable isotopes, $^{28}$Si (92.21%), $^{29}$Si (4.70%) and $^{30}$Si (3.09%). Thus only $^{30}$Si produces a radionuclide by the usual (n,γ) reaction of thermal neutrons. $^{31}$Si produced by the $^{30}$Si(n,γ)$^{31}$Si reaction has a 2.62-h half-life and very few γ-rays, with an intensity of only 0.07% (1.26 MeV). Considering the low abundance, the relatively low cross-section (0.28 b) and mainly the low intensity of the γ-rays, $^{31}$Si does not present a large problem in instrumental analysis by γ-ray spectrometry. However, owing to the presence of fast and epithermal neutrons in the reactor, the main activity induced in silicon is due to $^{28}$Al, $^{29}$Al and $^{27}$Mg formed by the reactions $^{28}$Si(n, p)$^{28}$Al, $^{29}$Si(n, p)$^{29}$Al and $^{30}$Si(n, α)$^{27}$Mg. As the half-lives of these radionuclides are short (2.3, 6.6 and 9.5 min, respectively), INAA is possible for radionuclides with half-lives longer than 1–2 h. In any case, the activity induced in nuclides with shorter half-lives is usually not sufficient to measure the required purity for electronic-grade semiconductors, owing to the small amount of radioactive atoms which can be formed until reaching saturation. As there is no background from the Si matrix after about a day or two and since the concentrations of the trace elements are low, the ways to increase the sensitivity (decrease the lower limit of detection) are to irradiate with a larger total number of neutrons (higher flux, longer irradiation times or both). In the high flux reactor (HFR) at Petten, the

*a* Verheijke et al.(35) irradiated wafers of 15 mm diameter and 0.5 mm thickness (20.6 g) with a flux of $4 \times 10^{13}$ n cm$^{-2}$ s$^{-1}$ for 72–96 h and counted for 6–8 h; Lindstrom(36) irradiated samples of 100 mg for up to 6 h at $5 \times 10^{13}$ n cm$^{-2}$ s$^{-1}$; Revel et al.(37) used 1 g of Si and irradiated for 72 h at $2.3 \times 10^{14}$ n cm$^{-2}$ s$^{-1}$; Fujingawa and Kudo(38) irradiated 5–10-g samples for 11 d at $2 \times 10^{13}$ n cm$^{-2}$ s$^{-1}$.  

Netherlands, a special irradiation facility was constructed for irradiation of silicon samples from Philips, in which silicon wafers of up to 15 cm in diameter can be irradiated with $4 \times 10^{13}$ thermal n cm$^{-2}$ s$^{-1}$ and the irradiation is done for 72–96 h.$^{34,35}$ They also used large Ge(Li) detectors (100–150 cm$^3$) and counted for 8–16 h, and obtained the lowest detection limits. Table 1 summarizes some of the limits of detection given in the literature for an Si matrix.$^{35–39}$ For some elements, e.g. Cl and Mn, shorter irradiations were used, between 0.5 and 2.0 h. A special correction has to be done in the case of the determination of Na owing to the reaction $^{28}$Si(n, p)$^{24}$Na, as was shown by Niese$^{40}$ by irradiating very pure Si in a reactor core with and without a Cd cover to absorb the thermal neutrons. The contribution of the $^{28}$Si(n, p)$^{24}$Na reaction to $^{24}$Na in a silicon matrix depends on the spectrum of the neutrons in the reactor core, as very high energy is required for this reaction and the Q value exceeds that of a 14-MeV neutron generator.$^{40}$ Niese found$^{40}$ that the contribution of the $^{28}$Si(n, p)$^{24}$Na reaction is equal to 0.7 ppb. For the HFR at Petten, The Netherlands, the contribution is 0.55$^{35}$ or 0.6 ppb.$^{34}$ Revel et al.$^{57}$ found this contribution of the $^{28}$Si(n, p)$^{24}$Na reaction to be <0.4 ppb. Haas et al.$^{41}$ warned against the common use of wrapping the sample for irradiation in Al foil, as they showed that there is recoil of $^{24}$Na from the Al wrapping to the sample, due to the high recoil energy from the $^{27}$Al(n, a)$^{24}$Na reaction.

In many other uses it is not important, but owing to the very low concentration of Na in pure Si, this contribution might be considerable.

Several important elements cannot be determined in this method, including mainly the light elements H, Li, Be, B, C, N, O and F as they do not form radioisotopes or they are too short lived. Phosphorus cannot be determined in this way owing to a lack of $\gamma$ emission from the only produced $^{32}$P; however, $^{32}$P $\beta$-rays can be determined destructively by the extraction of the phosphomolybdic complex in the presence of hold-back carriers of Tl and Au.$^{42}$ The chemical yield of the extraction was found to be $83.8 \pm 4\%$ and the decontamination factors were 79–6500 for the different elements studied. The limit of detection was found to be $3 \times 10^{-11}$ g. They carried out their study$^{42}$ for phosphorus-doped silicon and Alfassi and Yang$^{43}$ showed that for this case, there is no need for chemical separation and 10–20 d of cooling are sufficient to ensure that the only $\beta$ emitter is $^{32}$P (with an accuracy of 1–2%, which is much better than the reproducibility of the extraction yield). The limit of detection should be about the same, as both methods use liquid scintillation counting for the measurement of the $\beta$ activity, although Alfassi and Yang used a discriminator which reduces the detection limit by a factor of two.

**5.5 An Example of Interference Removal in Instrumental Neutron Activation Analysis: Determination of Platinum in Aerosols**

Pt is emitted into the air by corrosion of the catalytic converters used in cars to reduce the emission of CO, NO$_x$ and unburned hydrocarbons. In order to determine the concentration of Pt in the air, a high-volume air-pump pumps air through a filter and the amount deposited on the filter (together with the aerosols) is determined. Pt can be determined via several radionuclides. $^{199}$Pt suffers from very low abundance (0.01%) of the parent stable nuclide, $^{198}$Pt. $^{197}$Pt and $^{199}$Pt suffer from relatively short half-lives (18.3 h and 30.8 min). If a measurement is made shortly after the irradiation, these IRNs could not be observed owing to the large amounts of Compton-scattered photons from the major elements Na, Cl and Br. Thus Pt can be determined in minute amounts only via $^{199}$Au [3.14 d, 158.4 keV (36.9%)] , which is formed by the sequence of reactions in Equation (47):

$$^{199}$Pt(7.2\%) $\rightarrow$ $^{199}$Pt $\rightarrow$ $^{199}$Au \quad (47)$$

$^{199}$Au suffers from the two kinds of interferences mentioned earlier: (1) it can be formed also from other elements besides Pt and (2) another radionuclide formed from other elements have a very close $\gamma$ line. In the following paragraphs we will show how these interferences can be overcome.

1. $^{199}$Au can be formed also from the successive absorption of two neutrons by $^{197}$Pt owing to the very high cross-section for the (n, $\gamma$) reaction of $^{198}$Au (26 500 b) and the high cross-section for the (n, $\gamma$) reaction of $^{197}$Au (98.7 b) [Equation 48]:

$$^{197}$Au $\rightarrow$ $^{198}$Au $\rightarrow$ $^{199}$Au \quad (48)$$

Since $^{198}$Au is a radionuclide with a close half-life to $^{199}$Au (2.69 d), it can be measured simultaneously with $^{199}$Au, and can be used to calculate the concentration of Au in the sample and hence to calculate the contribution of Au to the measured peak of $^{199}$Au. Subtracting this contribution, we obtain the counts of $^{199}$Au formed from $^{198}$Pt and hence the concentration of Pt.

2. Another problem is the very close $\gamma$ lines of $^{199}$Au (158.4 keV) and $^{40}$Ca (159.3 keV). If similar counts are obtained for the two radionuclides, the $\gamma$ spectrum shows clearly two distinct peaks, although the lower one (158.4 keV) does not go to zero, and hence there is lower accuracy in the calculation of the area under each peak (i.e. the counts due to each radionuclide). The situation is worse when the number of counts
of one of the radionuclides is considerably higher (ratio > 4), in which case the spectrum does not show two distinct peaks but one peak with a shoulder, more or less visible. In order to separate this composite peak into its two contributions, two methods can be used. An important remark concerning this measurement is not to use a computer convolution program to calculate the area of this peak, as it will be programmed with a fitting function which is characteristic for a pure photopeak. In this case it is better to calculate the area by a simple integration of the counts under the peak, subtracting a trapezoid for the background correction. The two methods for separation of the contributions are based on (i) the different temporal behaviors of the two contributions and (ii) another γ line which allows the calculation of the contribution of one radionuclide to the mixed 158.4–159.3 keV peak, facilitating the calculation of the contribution of the other one by subtraction.

(a) Temporal separation: although $^{199}$Au and $^{47}$Sc have close half-lives which usually will not allow the temporal separation of their contributions, their parents [as none of them is produced directly from the (n,γ) reaction and are products of β decay of the (n,γ) products] have considerably different half-lives and hence the two contributions can be separated by measuring twice and solving the two equations (obtained by writing equations for the expected counts, writing x and y for the masses of Pt and Ca) with the two unknowns $m_{Pt}$ and $m_{Ca}$ (or x and y, $x = m_{Pt}$ and $y = m_{Ca}$) [Equations 49 and 50]:

$$^{198}$Pt $\rightarrow^{199}$Pt $\rightarrow^{199}$Au \hspace{1cm} (49)$$

$$^{46}$Ca $\rightarrow^{47}$Ca $\rightarrow^{47}$Sc \hspace{1cm} (50)$$

The disadvantage of this method is the need to make two measurements, hence the counting time required is more than doubled, since due to the decay between the two measurements the counting time of the second one must be longer than the first one in order to obtain the same statistical accuracy.

(b) $^{47}$Sc does not have a γ peak without interference to calculate its contribution to the composite peak; however, its parent $^{47}$Ca has a good γ line at 1297 keV without interference and this γ line can be used to measure the concentration of Ca and consequently its contribution via $^{47}$Sc to the 158–159-keV peak.

The above contributory interferences are the only ones in a well-moderated nuclear reactor (heavy water moderated), while in most research reactors (light water moderated) the high-energy neutron flux will lead to additional interferences by the $^{47}$Ti(n,p)$^{48}$Sc and $^{199}$Hg(n,p)$^{200}$Au reactions. These interferences can be removed by additional irradiation inside a box made of B or Cd, which are thermal neutron absorbers, as explained in sections 5.6 and 5.7. However, this correction is not mandatory in most cases. The $^{199}$Hg(n,p)$^{199}$Au reaction can be neglected as the cross-section is lower than for (n,γ) and the fast flux is smaller than the thermal flux and the Hg concentration is low. The $^{47}$Ti(n,p)$^{47}$Sc reaction can be a greater problem owing to the higher concentration of the more abundant Ti. However, since Ti has several isotopes, the measurement of $^{48}$Sc, which can be formed only by the $^{47}$Ti(n,p)$^{47}$Sc reaction, can be used to calculate the contribution of the $^{47}$Ti(n,p)$^{47}$Sc reaction.

5.6 Epithermal Instrumental Neutron Activation Analysis

In the usual INAA, the whole reactor neutron energy spectrum is used. However, in some cases, the use of part of the neutron spectrum is preferable; these systems are characterized by large differences in the activation cross-sections for the desired and the interfering nuclides in the various parts of the energy spectrum. The required trace elements are activated with part of the neutron spectrum while the interfering major elements are activated more strongly with the other parts of the spectrum, and thus we prefer to avoid this second part.

The neutron energy spectrum in a nuclear reactor is usually divided, for convenience, into three portions, and their relative abundances are dependent on the reactor structure. The most abundant fraction is the one of thermal neutrons, i.e. those neutrons which are in thermal equilibrium with the moderator atoms. Their most expected energy is equal to $kT$ (where $k$ is Boltzmann’s constant and $T$ is the neutron temperature), which at room temperature is equal to about 0.025 eV. The neutrons with energy above that of the thermal neutrons are divided into fast neutrons, those which are directly from fission and have not been moderated at all with energy mainly above 1 MeV, and epithermal neutrons, i.e. partly moderated and having energy between tenths of an electronvolt and 1 MeV. When the whole reactor neutron energy spectrum is used for activation, the main contribution is from the thermal neutrons, also owing to their usually higher cross-section [(n,γ) reactions].

A special case where advantage can be taken of the epithermal and fast neutrons is the case where the required trace elements are activated more strongly...
relative to the major elements by the epithermal or fast neutrons. Most major elements in geology and biology follow the $1/\nu$ cross-section rule (their activation cross-section is inversely proportional to the square root of the neutron energy) throughout the whole energy spectrum. On the other hand, many of the less abundant elements have, in addition to their thermal activation, large activation cross-section resonances in the epithermal energy region and consequently can be activated preferentially in this region. Similarly, several of the less common elements can be activated by other neutron reactions besides the common $(n,\gamma)$ reaction. These $(n,p)$ and $(n,\alpha)$ reactions require higher energy than thermal reactions (and in most cases they do not occur also in the epithermal region and are induced only by fast neutrons).

A simple example of the advantage of using neutron filters (thermal neutron absorbers) in activation analysis is seen in Figure 5(a) and (b), which shows the $\gamma$-ray spectra of a sample of blood serum, activated with reactor neutrons once within a cadmium wrapping and once without any absorber (bare irradiation).\(^{(44)}\) In the case of activation without a Cd absorber, the Compton-scattered photons of the major elements Na and Cl cover the peaks of bromine and iodine (bromine can be determined only after a delay of several days while the shorter-lived iodine cannot be determined instrumentally and can be determined only after chemical separation). The activation with epithermal neutrons (Cd cover) shows clearly the peaks of Br and I. A more complicated (geological) sample irradiated with and without a Cd cover is shown in Figure 6.

Owing to the presence of both thermal and epithermal neutrons, the product $\phi \phi$ in Equation (28) should be replaced by the term $\phi_{th} \sigma_{th} + \phi_{epi} I_0$, where $\phi_{th}$ and $\sigma_{th}$ are the flux and cross-section of the reaction with thermal neutrons and $\phi_{epi}$ and $I_0$ [the resonance integral of the

0.55 eV as it is the cut-off in neutron absorption by Cd,
as fast neutrons rather than epithermal neutrons, and
neutrons with energies above 1 MeV are categorized
The boundaries of 0.55 eV and 1 MeV were chosen since
once covered by an absorber of thermal neutrons. Thus
this nuclide irradiated once bare (without a cover) and
ratio. The absorber ratio is the ratio of the activities of
nuclide [Equation 54]:
where \( R_{\text{Cd}} \) is the cadmium ratio as defined previously
and the superscripts 0 and i stand for the measured
and the interfering nuclides, respectively. This is the
most commonly used advantage factor and several tables
of this factor for many nuclides have appeared in
the literature for cadmium absorbers and for boron
absorbers.\(^{45–48}\)

5.6.1 Brune and Jirlow’s Advantage Factor
Brune and Jirlow\(^{45}\) suggested the use as an advantage
factor for ENAA activation of the ratio between the
cadmium ratio of the measured nuclide and the interfering
nuclide [Equation 54]:
\[
F_{\text{BJ}} = \frac{R_{\text{Cd}}}{R_{\text{Cd}}} \tag{54}
\]
where \( R_{\text{Cd}} \) is the cadmium ratio as defined previously
and the superscripts 0 and i stand for the measured
and the interfering nuclides, respectively. This is the
most commonly used advantage factor and several tables
of this factor for many nuclides have appeared in
the literature for cadmium absorbers and for boron
absorbers.\(^{45–48}\)

5.6.2 Parry’s ‘Improvement Factor’
Parry\(^{49}\) pointed out that while the advantage factor
describes well the increase in the signal-to-noise ratio,
it does not consider the decrease in the activity of the
analyzed element due to the elimination of the activation
by the thermal neutrons and hence does not treat the
larger error resulting from the lower counting statistics.
Parry suggested that the true criterion should be the
improvement in the detection sensitivity. The lower
detection limit, \( L_D \), for a radioactivity measurement,
i.e. the minimum signal which can be detected above
the background at the 95% confidence level is given by
Equation (55):\(^{50}\)
\[
L_D = 2.33\sqrt{B} \tag{55}
\]
where \( B \) is the background activity. The minimum
detected mass in activation analysis (sensitivity) is given by
Equation (56):
\[
M_D = \frac{A}{L_D} = \frac{A}{2.33\sqrt{B}} \tag{56}
\]
where \( A \) is the specific activity of the analyzed element
under the experimental conditions for the activation
and detection. Since \( A \) is proportional to the activity
of the analyzed element and since \( B \) is due mainly to the
interfering nuclide, Parry suggested that the improvement
factor, \( f_p \), is given by Equation (57):
\[
f_p = \frac{R_{\text{Cd}}}{R_{\text{Cd}}} \tag{57}
\]
5.6.3 Bem and Ryan’s Advantage Factor

Bem and Ryan\(^{(51)}\) in 1981 followed the same trend of thinking as Parry; however, they suggested that the advantage factor should describe the improvement of the relative standard deviation of the counts. If the net counts (baseline corrected counts) is \(N\) and the background count is \(B\), the advantage factor is given by Equation (58):

\[
f_{BR} = \frac{1 + \frac{2B}{N^2}}{1 + \frac{2B}{N^2}}^{1/2}
\]

(58)

where the subscripts \(i\) and 0 have the same meaning as the superscripts earlier.

When the background is mainly due to the interfering radionuclide, Bem and Ryan’s advantage factor is equal to that of Parry. The correlation of Parry’s advantage factor with that of Brune and Jirlow can be seen from Equation (59):

\[
f_p = \frac{f_{BJ}}{\sqrt{R_{Cd}^2}}
\]

(59)

Therefore, Parry’s advantage factor is always smaller than that of Brune and Jirlow.

5.6.4 Tian and Ehmann’s Generalized Advantage Factor

Tian and Ehmann\(^{(52)}\) criticized Bem and Ryan’s criterion (and consequently Parry’s) on the grounds that in practice, in INAA, the limit on the number of counts is not due to the activity of the analyte, but rather to problems associated with the high counting rate. A high count rate leads to inferior resolution and also to problems of pile-up and dead time of the electronic system. In order to overcome these problems, the samples are measured far from the detector or are irradiated for shorter times. When the sample is activated with only epithermal neutrons, the total activity of the sample is reduced considerably, and hence the counting efficiency can be increased by using a smaller sample–detector distance, or the total counts can be increased by using larger samples or longer irradiation times. If the increase in counts (due to either count efficiency or size of the sample or length of irradiation) is given by \(G^2\), then the generalized Tian and Ehmann’s advantage factor is given by Equation (60):

\[
f_{TE} = G \frac{R_{Cd}^2}{R_{Cd}^2}
\]

(60)

If \(G = 1\), \(f_{TE} = f_p\), and if \(G = \sqrt{R_{Cd}^2}\), then \(f_{TE} = f_{BJ}\). The last case is the practical one, since both in the thermal activation and in the epithermal activation, the counting efficiency is usually chosen to obtain the maximum total counting rate allowable by the dead-time correction device. This generalized approach of Tian and Ehmann\(^{(52)}\) gives a firmer basis for the widely used definition of Brune and Jirlow.

5.6.5 Thermal Neutron Absorbers

The main absorbers for the thermal neutrons are cadmium and boron owing to their high cross-section for reaction with thermal neutrons. The variation of the cross-section with the energy is different for Cd and for B, hence an intelligent choice of an absorber (also sometimes called a filter) will lead to optimized detection of some nuclides.\(^{(53)}\) In some cases, one absorber is used and in others a combination of two absorbers, e.g. Cd + B.\(^{(49,53,54)}\) In some experiments, filters which absorb the epithermal neutrons in some regions are used, allowing more selectivity for some elements.\(^{(55)}\)

Since the main absorbers are boron and cadmium, it is very important to compare them from the technical point of view. The absorber can be used as a covering sheet, wrapping the sample in it, mainly in the case of cadmium for which metallic sheets are commercially available, or as a capsule built from these materials, or as a mixture with the sample, used with \(B_2O_3\);\(^{(56)}\) or as a permanent lined installation inside one of the irradiation ports of the reactor. The use of absorber-lined ports has the disadvantages that (1) scattered thermal neutrons can come from angles which are not covered by the lining of the absorber, leading to lower absorber ratios, whereas when the absorber is used as a capsule or wrapping, it is covered from all angles, and (2) the capsule in which the sample is held during the pneumatic transfer and which usually is made of polyethylene leads to partial thermalization of the epithermal neutrons. On the other hand, the use of an absorber-built capsule or wrapping suffers from the disadvantages of the absorption reactions. Cadmium is activated to short- and long-lived nuclides and the unloading and unpacking of the sample for medium- and long-lived radionuclide measurement faces radiation safety problems owing to the high radiation dose. Short-lived (\(t_{1/2} < 20–30\) s) radionuclides cannot be measured at all in a cadmium capsule since the short half-life prohibits the safe unpacking of the vessel and the activity of the absorber is too high to allow measurement together with the filter.

While the absorption of neutrons by \(^{10}\)B does not lead to radioactive products, the reaction \(^{10}\)B(\(n,\alpha\))\(^7\)Li is very exoergic \((Q = 2.792\) MeV\) and the samples are heated considerably. Stroube et al.\(^{(57)}\) found that in the 20-MW reactor at the former US National Bureau of
Standards (NBS), thermal heating of the boron nitride vessel limited the length of irradiation for freeze-dried foods to 4 s and prevented completely safe irradiation of wet food. When biological samples are irradiated, this heating accelerates the thermal decomposition of organic compounds, producing high pressure in the sample container, which may explode and contaminate or even ruin the irradiation port. In other cases, elements may be volatilized and lost. In order to avoid these effects, the time of irradiation should be limited. Williamson et al.\(^6\) measured the temperature inside a polyethylene rabbit inserted into a Cd-lined irradiation port and found that the temperature reached an equilibrium value of 90 °C in about 7 min. When a BN capsule was irradiated in the same position, the measured temperature was 120 °C in about 3 min and continued to rise. Ehmann et al.\(^7\) irradiated rock samples in a boron carbide filter for 20 h, keeping the sample in heat-sealed quartz ampules. Quartz, being a poor thermal conductor, keeps the sample from being highly heated; this solution is good for geological samples but will probably not suffice for biological samples. Chisela et al.\(^8\) studied the temperature in a sintered BC capsule in an air-cooled irradiation facility and found the capsule to reach steady-state temperatures of 163 and 194 °C for 4.0- and 5.0-MW reactors, respectively. When a permanent installation from powdered B\(_4\)C was made with water coolant, the temperature reached not more than 50 °C.

The use of a permanent lining of absorber also has the disadvantage of reducing the total flux of the neutrons in the reactor and of excessive use of the nuclear fuel. A possible advantage of boron over cadmium is the reuse of the same filter in subsequent irradiation. Cadmium filters usually cannot be reused, at least immediately, owing to the long-lived radioactivity produced in cadmium during irradiation. The activity produced in boron filters is small and is due only to contamination in the boron. Unfortunately, boron carbide is extremely hard and is not machinable, and a capsule can be made only by the hot pressing process.

One of the disadvantages of boron filters is the impurities found in boron powder, as discussed in detail by Bem and Ryan.\(^9\) However, if a boron capsule is used together with a permanently installed Cd lining, the interferences due to the activities of \(^{28}\)Al, \(^{56}\)Mn and \(^{36}\)Cl from the boron contaminants are significantly reduced.\(^{10}\) Both cadmium and boron have high absorption cross-sections for low-energy neutrons; however, the energy dependences of the cross-sections differ considerably. Cadmium approaches a perfect sharp filter for the thermal region and has some resonance in the epithermal range, whereas boron behaves as almost a perfect \(1/\nu\) absorber with no sharp energy cut-off. Although the cross-section for neutron capture by boron is lower than the cross-section for absorption by cadmium in the lower energy range of 0.01–1 eV, it can be compensated for by using thicker boron absorbers. A 0.25 cm thick boron shield is sufficient to stop practically all the thermal neutrons. The effective cut-off energy is almost independent of the thickness of the Cd absorber whereas it increases considerably with increasing thickness of the boron absorber.

5.7 Fast Neutron Instrumental Neutron Activation Analysis

The reactions that occur with fast neutrons with energy usually in the megar electronvolt range should be looked upon in two ways: (1) the use of these reactions for the determination of some elements and (2) the possible interference of these reactions in the determination of some elements by (n,\(\gamma\)) reactions, due to the formation of the same nuclide as was shown earlier dealing with nuclear interferences. These interferences can be solved only by the use of double irradiation, one with a bare core and one inside a Cd or B filter, and calculating the contribution of each element. The same treatment is usually applied with the use of (n,p) and (n,\(\alpha\)) reactions in the determination of some elements. The main advantage of these reactions is that they produce nuclides different from those produced by (n,\(\gamma\)) reactions. Consequently,
they may lead to a faster determination in the case of producing a short-lived nuclide rather than the long-lived nuclide produced in \((n,\gamma)\) reactions. In other cases, they may allow the determination of elements which cannot be measured via \((n,\gamma)\) reactions since the radionuclide produced is only a \(\beta \) emitter.

### 5.7.1 Rapid Determination of Iron

Figure 7 shows the \(\gamma\)-ray spectrum of an iron sample irradiated for a short time.\(^{(62)}\) As can be seen, the peak of 847-keV \(\gamma\)-rays of \(^{56}\text{Mn}\) due to the \(^{56}\text{Fe}(n,p)^{56}\text{Mn}\) reaction is considerably higher than the \(^{58}\text{Fe}(n,\gamma)^{58}\text{Fe}\) 1099-keV peak. Hence the use of \((n,p)\) reactions for the determination of iron has a higher sensitivity in the case of short irradiation and counting. However, \(^{56}\text{Mn}\) is formed also from manganese by the \(^{55}\text{Mn}(n,\gamma)^{56}\text{Mn}\) reaction. The concentrations of both iron and manganese can be found by double irradiation, one sample with reactor neutrons (without any filter) and one sample with epithermal neutrons (with a cadmium absorber). If the specific activity (measured counts under the experimental setup per gram of the element) for irradiation with reactor neutrons will be \(F_R\) and \(M_R\) for iron and manganese, respectively, and similarly for epithermal neutrons \(F_E\) and \(M_E\), then the activity of 1 g of sample containing \(P_F\)% of iron and \(P_M\)% of manganese will be given by Equations (61) and (62):

\[
C_R = \frac{F_R P_F + M_R P_M}{100}
\]

\[
C_E = \frac{F_E P_F + M_E P_M}{100}
\]

where \(C_R\) and \(C_E\) are the activities induced by reactor neutrons and epithermal neutrons, respectively. The solution of these two equation gives Equations (63) and (64):

\[
P_F = \frac{M_E C_R - M_R C_E}{\Delta}
\]

\[
P_M = \frac{F_R C_E - F_E C_R}{\Delta}
\]

where \(\Delta = 100(F_R M_E - F_E M_R)\).

### 5.7.2 Determination of Phosphorus and Silicon

Thermal neutron activation cannot be used for the determination of phosphorus and silicon. A radiative capture \((n,\gamma)\) reaction with the only stable isotope of P leads to the formation of \(^{32}\text{P}\), which is a pure \(\beta \) emitter. In the case of silicon [stable isotopes \(^{28}\text{Si} (92.2\%), \,^{29}\text{Si} (4.7\%)\) and \(^{30}\text{Si} (3.1\%)]\), the only radionuclide produced by the \((n,\gamma)\) reaction is \(^{31}\text{Si}\), which is almost only a \(\beta \) emitter. Its very low intensity of \(\gamma\)-rays (1266 keV, 0.07%) together with the low abundance of \(^{30}\text{Si}\) and the low cross-section for radiative capture (0.11 b) permit only the determination of relatively large amounts of silicon. However, activation with epithermal neutrons leads also to the formation of \(^{28}\text{Al}\) via both \(^{31}\text{P}(n,p)^{28}\text{Al}\) and \(^{28}\text{Si}(n,p)^{28}\text{Al}\) reactions and of \(^{29}\text{Al}\) by the \(^{29}\text{Si}(n,p)^{29}\text{Al}\) reaction. \(^{28}\text{Al}\) is also produced by the \(^{27}\text{Al}(n,\gamma)^{28}\text{Al}\) reaction. This leads to a procedure for the determination of Si from the activity of \(^{29}\text{Al}\), which is produced only from silicon, using the activities of \(^{28}\text{Al}\) from activation with a Cd filter and without a filter to determine the concentration of both aluminum and phosphorus.

However, the activity of \(^{29}\text{Al}\) produced for Si is almost two orders of magnitude less than the activity of \(^{28}\text{Al}\) produced from it. Hence the use of \(^{29}\text{Al}\) will both limit the minimum amount of silicon that can be determined and will reduce the accuracy of the measurement. Another problem associated with the measurement of \(^{29}\text{Al}\) is that its main \(\gamma\) line is the 1273-keV line, which suffers from the interference of the SE peak of the more abundant \(^{28}\text{Al}\) at 1268 keV.

However, when the concentration of Si is high, silicon can be determined by the \(^{28}\text{Si}(n,p)^{28}\text{Al}\) reaction, as was done by Hancock\(^{(63)}\) for the measurement of silicon in pottery using a Cd shield to decrease the formation of \(^{28}\text{Al}\). The samples were allowed to decay for 17–20 min before counting, to decrease the \(^{28}\text{Al}\) activity further. Ördög et al.\(^{(64)}\) measured in that way the concentration of silicon in very small inhomogeneous lymph-node samples. The concentration...
of P was determined spectrophotometrically by the molybdenum blue method and hence the concentration of Si and Al can be found from the $^{28}\text{Al}$ activity induced by both epithermal activation (Cd cover) and reactor neutron irradiation. Another way was suggested by Alfassi and Lavi,\(^{(65)}\) who used the simultaneous determination of $^{27}\text{Mg}$ and $^{28}\text{Al}$, each of them for both reactor activation and irradiation with only epithermal neutrons, to measure simultaneously Mg, Al, Si and P. Each of these radionuclides can be formed by three reactions (Scheme 5).

![Scheme 5](image)

5.8 Instrumental Neutron Activation Analysis with Emissions Other than $\gamma$ Emission

As written earlier, in most delayed activation analysis only the $\gamma$ emission is measured, since it is difficult to distinguish between $\beta^-$ emitters, owing to their extended spectra rather than monoenergetic emission. X-ray emission is less penetrating and neutron emission is very rare. However, all these emissions can be used in special cases. For $\beta^-$, it was shown that both for biological samples\(^{(66)}\) and most geological samples,\(^{(67)}\) owing to the higher concentration of P, the main relatively long-lived $\beta^-$ emitter is $^{32}\text{P}$, and after 10 days more than 95% of the $\beta^-$ emission is due to $^{32}\text{P}$, and hence the total $\beta^-$ measurement can be used for the determination of P.

5.8.1 X-Rays\(^{(68)}\)

X-rays suffer from two disadvantages, which can be turned to advantage in special cases. First, the range of X-rays is fairly short and only those emitted from the first few micrometers of the sample can be detected. This is disadvantageous when the whole bulk concentration is needed. However, it is advantageous when only the first few micrometers are important and when in them the concentrations of the measured elements are higher. Second, fewer nuclides emit X-rays (mainly after EC or internal conversion) than those emitting $\gamma$-rays. This is disadvantageous since fewer elements can be determined in this method. However, if the major elements of the sample, which interfere with the measurement of the trace elements, do not emit X-rays, the few elements which emit X-rays can be determined even at low concentration owing to the lower background.

Owing to the low penetration of X-rays, the samples used for X-ray measurements should be very thin. The X-rays can be due to internal conversion (X-rays of the Z of the IRN), EC (X-rays of Z – 1 element) or internal conversion after a $\beta$ decay (Z + 1 element). In $\gamma$-ray spectrometry the electrons emitted by the active sample are stopped by a thin Perspex or aluminum foil as the electrons emitted by the active sample are less penetrating than $\gamma$-rays. In the case of low-energy X-rays, they are less penetrating than some of the electrons and the electrons should be removed by a magnetic field.\(^{(69–71)}\) X-ray measurements have been used mainly for the determination of rare earths in geological samples,\(^{(72–74)}\) copper\(^{(75)}\) and bromine\(^{(76)}\) in biological and geological samples, but also other elements, such as Nb in steel\(^{(77)}\) and Co and Hg in Dead Sea water,\(^{(78)}\) have been determined.

5.8.2 Neutrons\(^{(79)}\)

Delayed neutrons are emitted from only very few radionuclides. In many cases the radionuclide decays by both $\beta^-$ and neutron emission. For example, $^{87}\text{Br}$ decays 2.8% by neutron emission while $^{88}\text{Br}$ decays 6.6% by neutron emission and $^{88}\text{Se}$ only 0.8%, $^{90}\text{Br}$ decays 25% by neutron emission. At least 57 radionuclides which emit neutrons are known, but none of them is
formed by an \((n,\gamma)\) reaction since the nuclides should be more than one neutron further from the line of stability in order to emit neutrons. However, those radionuclides can be formed in a neutron-induced fission of fissile nuclides such as \(^{235}\text{U}\), since the heavy elements have a higher percentage of neutrons in the nucleus. This is the reason why activation analysis followed by measurement of neutrons is used for the determination of only U and Th. Since other elements do not produce neutron emitters, the background from other elements is very small. The neutrons are measured (after their moderation in a paraffin layer) by BF\(_3\) counters. These are gaseous ionization chambers which measure the \(\alpha\)-particles formed by the \(^{10}\text{B}(n,\alpha)^{7}\text{Li}\) reaction. Outside \(\alpha\)-particles are not able to penetrate the counter walls. At least 57 delayed neutron emitters are formed in the neutron-induced fission with half-lives ranging from 0.08 to 55.6 s. In order to get rid of the \(^{17}\text{N}\) (4.16 s) and neutron-induced fission with half-lives ranging from 0.08 to 80 s.

### 5.9 Depth Profiling by Instrumental Neutron Activation Analysis

Depth profiling involves the measurement of the concentration of a trace element as a function of its distance from the surface of the sample. This can be done by a destructive method in which the whole sample is activated and then divided into a number of sections of varying distances from the surface, either by gradual slow dissolution or by gradual milling and grinding (for each layer, its thickness and \(\gamma\) or \(\beta\) activity of the various elements are measured). Many samples are too important to be destroyed in the measurement. Using \((n,\alpha)\) or \((n,p)\) reactions, the depth profiling can be done nondestructively. The emitted charged particle (\(\alpha\) or \(p\)) has a definite kinetic energy. This particle, while transversing in the material, from its place of formation inside the sample to the detector positioned in front of the sample, loses part of its energy, depending on the distance it traveled in the sample. From the measured energy, the distance from the surface can be calculated. Thus, the energy spectrum measured for this particle is related to the concentration depth profile of the element, which is responsible for this nuclear reaction.

In order to allow the measurement of low concentrations, the nuclear reaction should have a high cross-section of the order of at least 10 fb. These high cross-sections rule out most elements and only very few elements can be determined.

The method was developed in 1972 by Ziegler et al.\(^{(82)}\) for the determination of boron due to the high cross-section of the \(^{10}\text{B}(n,\alpha)^{7}\text{Li}\) (\(\sigma = 3837\) b). This cross-section is five orders of magnitude larger than that of almost any other stable nuclide for \((n,\alpha)\) reactions (except \(^{6}\text{Li}\)). The measured sample is placed in a vacuum chamber (pressure \(< 5 \times 10^{-6}\) Torr). They needed only about \(10^{11}\) neutrons to detect a concentration of 100 ppm of boron in a 2-cm Si wafer. The \(^7\text{Li}\) is produced in both the ground state (6%) and in the 479-keV excited state (94%). The energy is distributed between the \(\alpha\)-particle and the \(^7\text{Li}\) according to their masses (1471 and 839 keV for \(^4\text{He}\) and \(^7\text{Li}\) in the reaction leading to the excited states). The bombarding thermal neutron passes through the Si wafer (170 \(\mu\)m thick) with negligible attenuation, so that the reaction efficiency is independent of the depth. The neutron beam was collimated to produce a spot 1 cm radius at the target chamber (neutron flux \(2.3 \times 10^{10} \text{n cm}^{-2} \text{s}^{-1}\)). The targets were mounted at a 45° angle to the neutron beam. The \(\alpha\)-particles were detected by a surface barrier detector subtending an angle of 19 msr and was specially fabricated to have a low \(\gamma\) and electron background and to be able to measure the spectrum of the \(\alpha\)-particles in the presence of \(^7\text{Li}\), although this led to poorer energy resolution for the \(\alpha\)-particles [full width at half-maximum (fwhm) \(\approx 20\) keV instead of 12–14 keV]. The depth of the boron is determined by the energy loss of the 1471-keV \(\alpha\)-particles using the known specific energy loss, \(dE/\text{dx}\). An energy, \(E_{\text{tr}}\), parallel to depth is given by Equation (69):

\[
\text{depth} = \frac{E_{\text{tr}}}{1471} \frac{dE}{dx} \text{d}E \tag{69}
\]

Ziegler et al.\(^{(82)}\) measured the energy spectra of \(10^{15} – 10^{16}\) \(^{10}\text{B}\) atoms per square centimeter and calculated a concentration resolution of 3 ppm and a depth resolution of 20 nm. M"uller et al.\(^{(83)}\) used the high-flux reactor of ILL, Grenoble, France, with a collimated flux of \(1.04 \times 10^9 \text{n cm}^{-2} \text{s}^{-1}\) and 1.5 cm diameter, a detector with resolution of better than 16 keV for the 1471-keV peak. For a counting time of 1000 min, \(10^{11}\) \(^{10}\text{B}\) atoms per square centimeter will lead to about 110 integral counts. This is enough for measuring total boron concentration but not for profile determination and they estimated that for profile determination the minimum required concentration is \(10^{12}\) \(^{10}\text{B}\) atoms per square centimeter. They measured the concentration depth profiles of boron in silicon wafers implanted with \(10^{11}\), \(10^{13}\) and \(10^{14}\) \(^{10}\text{B}\) atoms per square centimeter and the accuracy of the depth determination was about 25 nm. It should be remembered that this is for \(^{10}\text{B}\) atoms whereas they constitute only 20% of the natural boron atoms. Kvitek et al.\(^{(84)}\) studied the boron concentration profile in Si using the spectra of both
α-particles and ⁷Li particles. As can be expected from the higher \( dE/dx \), the spatial resolution obtained with the 839-keV ⁷Li particle is better than that obtained by using the 1431-keV ⁴He line (by about 30%). However, in a later work, they explained⁸⁵ that in spite of the better resolution of the ⁷Li profiling, the fact that the ⁷Li line is located in the high-background region of the measured spectra often makes the profile analysis by this method difficult. In order to obtain better resolution they suggested measuring the \( α \)-spectra with different tilting angles.

Biersack et al.⁸⁶ discussed the achievable depth resolution and the main sources of uncertainties. They pointed out four main inherent uncertainties: (1) the uncertainty in the angle \( θ \) between the point of reaction and point of detection as the particle travel distance \( L \), \( L = x/\cos θ \), where \( x \) is the depth of the target atom; (2) the uncertainty in the energy resolution of the detector; (3) the uncertainty in energy loss due to energy loss straggling, assuming a fixed pathlength, \( L \); and (4) uncertainty due to multiple angular scattering. They concluded that for \((n,α)\) reactions, a depth resolution of 5 nm is feasible, and 10-nm depth resolution is feasible for \((n,p)\) reactions.

Apart from \( B \), the only element which can be determined in this way using the natural abundance is lithium with 7.4% ⁷Li, having a cross-section of 940 b for the reaction ⁶Li\((n,α)\) \( T \), with an \( α \)-energy of 2055 keV and a \( T \) energy of 2728 keV. Helium can be determined not for natural He but for ³He-doped substrates (stable isotope, natural abundance 0.0001%). Similarly, Na and Be can be determined with the radioactive isotopes ²²Na and ⁷Be, respectively, owing to their high cross-section.

Downing et al.⁸⁷ gave a detailed description of the neutron depth profiling (NDP) system and summarized the available data in various systems throughout the world. Special attention was paid to minimizing the contamination of the thermal neutron beams with fast neutrons and \( γ \)-rays. The amount of the \( γ \)-rays and fast neutrons was reduced by filtering the beam through 200 mm of sapphire single crystal and an 80-mm long silicon single crystal, which led to a ratio of cadmium to gold of \( >10^4 \) and a \( γ \) intensity of 200 mrad h⁻¹.

The NDP technique is quantitative and has few interferences in silicon-based materials. As a result, it is often used for calibration for other techniques. Other instrumental methods, such as secondary ion mass spectrometry (SIMS), Fourier transform infrared (FTIR) spectrometry, and Auger electron spectroscopy (AES) have greater sensitivity than NDP in most applications and better resolution in some matrices, but each of the other techniques is subject to highly interactive chemically and electronically induced artifacts. NDP can be used to calibrate the other methods and, after calibration, the better resolution of the other method can be used. Rutherford backscattering spectroscopy (RBS) and NDP complement each other as they both nondestructively analyze different compositions: RBS measures the concentration profile of heavy atoms in matrices of light atoms whereas NDP is limited to some light elements.

### 5.10 Practical Cases of Instrumental Neutron Activation Analysis

In section 5.4 a test case of INAA of Si was given. Si is one of the best matrices for INAA, owing to the low radioactivity induced in it by neutron irradiation, and consequently very low detection limits were obtained. This is not the case for all matrices. The following section gives details of several examples of analyses of various matrices by INAA.

Greenberg et al.⁸⁸ described the procedures adopted by the NAA group of the National Institute of Standards and Technology (NIST) in the USA. The samples are first packaged in a cleaned container. The container, depending on the type of the sample and the length of irradiation, can be polyethylene bags or vials, sealed by heating, or flame-sealed high-quality quartz (to eliminate as much as possible of the activatable sodium) or aluminum cans. The samples are irradiated in a well-moderated (by D₂O) neutron flux of \( 10^{14} \) n cm⁻² s⁻¹ using a pneumatic tube for transferring the sample to the reactor. The length of the irradiation, decay and counting depends on the analyzed elements. For one or a few elements the timings are optimized for these elements. Thus, for the determination of mercury in urine the samples (in quartz ampules) are irradiated for 1 h and counted after decay both of ⁵ and 20 d in order to measure the Hg content via the formation of both ¹⁹⁷Hg (\( t_{1/2} = 64.1 \) h, \( E_p = 77 \) and 191 keV) and ²⁰³Hg (\( t_{1/2} = 46.59 \) d, \( E_p = 279 \) keV). The long decay is used to reduce the activities of Na, Cl and Br.

To measure Cl and Br in various oils, they used short irradiation of a few minutes and measured the activity of ³⁵Cl (\( t_{1/2} = 37.2 \) min, \( E_p = 1642.2 \) and 2167.6 keV) after a decay of several minutes. The concentration of Br was determined via ⁵²Br (\( t_{1/2} = 35.3 \) h, \( E_p = 554.3 \) and 776.5 keV) after a decay of 24 h. For lower detection limits of bromine, irradiation from several hours up to 24 h was applied.

For a complete multielement analysis (20–40 elements which can be determined by NAA), the elements are divided into three groups according to the half-lives of their IRNs: 2 min –15 h, 0.5–5 d and >5 d.

Some elements appear in more than one group. The usual scheme of irradiations, decays and counting is followed. The same sample can be used for the two irradiations.
INSTRUMENTAL NEUTRON ACTIVATION ANALYSIS

</table>

The accuracy and precision of their determination can be found in Table 2, which gives their results for two NBS SRMs together with the certified values. The uncertainties listed represent the estimated overall analytical uncertainties at the 95% confidence level. SRM 1648 is Urban Dust and SRM 1572 is Citrus Leaves. In the column for the method, A, B and C refer to the previous scheme.

Cunningham and Stroube applied INAA to 240 food composites. They irradiated with a neutron flux of $4.9 \times 10^{13}$ nc cm$^{-2}$ s$^{-1}$. Two irradiations were done on each sample, one for 15 s and one for 4–5 h. For the short irradiation, a 2-min decay time and a 10-min counting time were used. For long irradiation, the decay times varied from 5 d to 4 weeks and counting times were 6–8 h. In the short irradiation they determined Ca, Cl, Cu, Ga, I, In, K, Mg, Mn, Na, S, Sr, Ti and V and in the long irradiation Ag, As, Au, Ba, Br, Cd, Ce, Co, Cr, Cs, Eu, Fe, Hf, La, Lu, Mo, Rb, Sb, Sc, Se, Sm, Ta, Th, W, Yb and Zn.

Sun and Jervis used a Slowpoke reactor, which is a nuclear reactor specially designed mainly for teaching, with activation analysis and the production of small amounts of radioisotopes in mind. The reactor operates at a low power of 20 kW and has a maximum flux of $10^{12}$ nc cm$^{-2}$ s$^{-1}$ (Sun and Jervis used a flux of $2.5 \times 10^{11}$ nc cm$^{-2}$ s$^{-1}$). An advantage of this type of reactor is its high stability (1–2% over long periods), which allows the irradiation of standards only every few days and not necessarily with each sample. Sun and Jervis determined 35 elements in rocks and soils using two irradiations and three countings. Al, Ba, Ca, Cl, Dy, I, Mg, Mn, Sr, Ti, U and V were determined by 1-min irradiation followed by 5-min counting after a decay of 10–15 min. Long irradiations of 16 h were followed by 30-min counting after 4–9-d decay (As, Br, K, La, Na,
Sb, Sm, W and Yb) and 100-min counting after a decay of 15–20 d (Ce, Co, Cr, Cs, En, Fe, Hf, Ln, Nd, Rb, Sb, Sc, Se, Sn, Ta, Tb, Th, Yb and Zn). Large relative standard deviations between several samples were found for Cl (32%), Sb (24%), Ti (18%), Ba (16%) and Br (14%), but for most elements the average relative standard deviation was <10%. A similar scheme was used by the same authors for samples of coal and ashes, except that the short irradiation time for coal samples was increased to 5 min.

Iskander\(^\text{92}\) measured the concentrations of 28 elements in tobacco and cigarette paper. Samples were irradiated for two irradiation periods, the first for 3 min and the second for 8 h with a neutron flux of \(2 \times 10^{12} \text{ nc m}^{-2} \text{s}^{-1}\) from a TRIGA Mark I reactor. The sample was irradiated for 3 min and was counted for 3 min after a 1-min decay (to measure Al, V, Ti, Ca and Mg) and after an additional decay of 26 min (total decay time 30 min) was counted again for 1000 s (to determine Cl and Mn). Also, the long-irradiated samples were counted twice: 4000 s after a decay of 12 h (to determine K, Na, As, Br and La) and 40000 s after a decay of 21 d (Ba, Rb, Th, Cr, Ce, Hf, Fe, Sb, Sr, Ni, Sc, Se, Zn, Cs, Co and Eu).

McOrist et al.\(^{93,94}\) studied trace element concentrations in various Australian opals. They irradiated their samples twice, for 1 min at a thermal flux of \(2.5 \times 10^{13} \text{ nc m}^{-2} \text{s}^{-1}\) and for 18 h at a thermal flux of \(5 \times 10^{12} \text{ nc m}^{-2} \text{s}^{-1}\). Each irradiated sample was counted twice. The short-irradiated samples were counted for 10 min after a 20-min decay and for 45 min after a decay of 24 h. After the long irradiation, the samples were counted for 2 and 4 h after 7 and 28 d of decay, respectively.

Wallner and Katzlberger\(^{95}\) studied the concentrations of 14 elements in spruce tree rings and needles from an area where an Al refinery used to be. Al, Mn, Ca and Cl were determined by 3–7 min of irradiation at a thermal neutron flux of \(5 \times 10^{10} \text{ nc m}^{-2} \text{s}^{-1}\). They calculated that for Al, assuming that the main interference for its 1779-keV line is from the Compton-scattered photons of the

a d means days, h means hours, s = seconds, m = minutes, mon = months, E means irradiation with epithermal neutrons.

2113-keV line of $^{56}$Mn, the optimum irradiation time is 4 min. However, for samples with a low Ca content longer irradiations up to 7 min were used. Na, K, Rb, Ba, Zn, Fe, Sc, Cr, Co and Br were determined by 10 h of irradiation with a thermal neutron flux of $8 \times 10^{13}$ n cm$^{-2}$ s$^{-1}$. The samples were counted three times, after a decay of 4–5 d (Na and K), a decay of 7 d (Br and Ca) and a decay of 14 d (Ba, Co, Cr, Fe, Rb, Sc and Zn).

Oddone et al. studied the elemental content of Anatolian obsidians, volcanic glasses, by INAA using both thermal and epithermal neutrons. Mg, K, Ca, Ti, Mn, As and Dy were determined by 2 min of irradiation at a thermal neutron flux of $1 \times 10^{12}$ n cm$^{-2}$ s$^{-1}$ in a TRIGA Mark II reactor, 250 kW. The sample was counted six times after decays of 0.5, 10, 30, 120, 480 and 960 min. The longer the decay time, the longer was the counting. Al and Si were determined by repeating the short-time irradiation for a sample wrapped in a 10-mm thick Cd foil. Both Al and Si were determined from the 1779-keV line of $^{28}$Al, using the epithermal neutron activation reaction $^{28}$Si(n,p)$^{28}$Al. Na, Ca, Sc, Cr, Fe, Co, Zn, Se, Rb, Zr, Nb, Sb, Ba, La, Ce, Nd, Sm, Eu, Gd, Tb, Ho, Tm, Yb, Lu, Hf, Ta and Th were determined by irradiation for 20 h. The samples were counted five times after decays of 3, 6, 24, 48 and 96 d. Epithermal neutron INAA was applied also with long irradiation (using samples inside a 1.5-mm thick Cd box) in order to reduce the interferences from elements with low resonance integrals and high thermal cross-section (small $I_0/\sigma$ ratio). The samples were irradiated for 40 h and counted five times after decays of 3, 6, 12, 24 and 48 d. The epithermal neutron INAA improved the sensitivity and accuracy of the measurement of Zn, Se, Rb, Zr, Nb, Sb, Cs, Ba, Gd, Tb, Ho, Tm, Yb, Hf, Ta and Th, Ni, Sr and U, which could not be measured by thermal INAA, could be determined by the epithermal INAA.

Sato suggested four different schemes of timings for the determination of various elements in biological samples (three times of irradiation with the last one being counted twice, after different decay times). His suggestion for the various elements is given in Table 3. Table 4 gives three examples from the literature, for the irradiation of biological samples together with their timings and the limits of detection of some elements via INAA.

Neutron radiography (NR) can be used to quantify the spatial distribution of water in the soil–plant system with high precision and good spatial resolution. This property of neutron imaging results from the high interaction probability of hydrogen nuclei with slow neutrons. If there is a sufficient difference between the water content of the soil and roots, neutron radiographs can reveal plant roots and show root development. NR is noninvasive, and the radiation dose needed to image plant roots in soil does not affect plant development. Quantification of the soil’s water content often requires correction for neutron-scattering artifacts. Root visibility is proportional to root thickness, and is inversely related to the width of the sample container and the water and organic matter contents of the ambient soil. Ideally, the soil should have low organic matter content and low water content but still permit the normal development of plant roots. Currently, the availability of neutron-imaging facilities limits the widespread application of NR to soil and root studies. However, technological development and increased investment will result in NR becoming a standard method for some soil–plant analyses.

1 INTRODUCTION

Terrestrial plants provide humanity with food and oxygen. Above- and belowground plant processes are equally important: while assimilation through photosynthesis occurs in the aboveground portions, the uptake of water and mineral nutrients occurs belowground. We have a limited understanding of some belowground processes because soil hinders the observation of plant roots. It is difficult to measure root development and water flux in the root zone without disturbing root growth or using artificial systems. Existing techniques include minirhizotrons, which are transparent plastic tubes inserted into the ground to view the roots, e.g. by using a video camera. Minirhizotrons interfere with the root environment and only provide an incomplete picture. X-ray radiography has insufficient contrast to reveal root–water interactions.

Willatt et al. showed that NR could reveal roots and root zone processes, without greatly perturbing the system, thus allowing sequential measurements. This is a critical advantage of NR over other techniques. However, the available technology in the 1970s gave images of insufficient quality and exposed the plants to radiation doses that were potentially harmful. Recent technological developments, especially improved beam collimation, detection systems, and image-processing techniques, have allowed the production of images with much higher contrast and spatial resolution while reducing the plants’ radiation exposure. These advances open up the possibility of using this technique to study root system development in soils and simultaneously monitor soil moisture distribution in near real time. Here, we describe the state of the art of NR as it relates to the analysis of plant–soil interactions.

2 NEUTRON RADIOGRAPHY CONFIGURATION

Figure 1 shows the configuration of a typical NR facility. NR requires a neutron source, which may be a reactor, the target of an elemental particle accelerator, or a neutron-emitting isotope. Thermal (12–100 meV) and cold (0.12–12 meV) neutrons are preferable for NR investigations. Therefore, epithermal, intermediate, and fast neutrons from the neutron source must be slowed...
down using a moderator such as heavy water. Neutrons enter a collimator that forms a neutron beam with specific geometric properties. The collimator may also contain filters that modify the energy spectrum of the beam or reduce the beam's content of γ rays. The neutron beam is transmitted through the sample onto a plane position-sensitive detector, which is usually a scintillation screen. A charge-coupled device (CCD) camera coupled to the detector records a two-dimensional image that is a projection of the object on the detector plane. The advent of high-resolution digital cameras has allowed fast imaging and increased resolution. Digital imaging techniques that use a CCD camera combined with image-processing tools nowadays yield quantifiable images with a resolution of about 100 \( \mu\)m. Lehmann et al.\(^\text{4}\) obtained a much higher spatial resolution with a special setup for microtomography. The required exposure time for such images is in the order of seconds. Images acquired using imaging plates or films (used until 1995) required several minutes of exposure to the potentially damaging neutron beam. The radiation dose received per image using modern techniques is about 0.003 mSv,\(^\text{5}\) which is some two orders of magnitude less than the minimum value of 0.2 mSv h\(^{-1}\) found to affect plant growth.\(^\text{6}\)

### 3 NEUTRON INTERACTIONS WITH THE PLANT–SOIL SYSTEM

NR is based on the Beer–Lambert exponential law of attenuation of radiation passing through matter\(^\text{7}\):

\[
I = I_0 \exp(-\Sigma_{\text{sample}}d)
\]

where \(I\) is the attenuated radiation (neutron) flux (cm\(^{-2}\) s\(^{-1}\)), after an incident neutron flux \(I_0\) passes through a material of thickness \(d\) (cm) with an attenuating coefficient \(\Sigma\) (cm\(^{-1}\)), which is a characteristic of the material. The attenuation coefficient, also called the macroscopic cross section, \(\Sigma\) (cm\(^{-1}\)), is related to the tabulated microscopic cross section \(\sigma\) (cm\(^2\)) as

\[
\Sigma = N\sigma
\]

with a nuclear density \(N\) (M). When a sample is placed in a neutron beam, heterogeneities in the composition and thickness of the sample result in variations in the intensity of the transmitted beam. Unlike X rays, neutron radiation interacts with atomic nuclei. There is no systematic change in the neutron attenuation coefficient with atomic number or mass. Each isotope has a specific neutron cross section, \(\sigma\), which is also energy dependent. Hydrogen has a neutron cross section some 10 times greater than deuterium and also greater than many other elements in the soil–plant system.

NR reveals structures in plant–soil systems owing to differences in the \(\Sigma\) values of the system’s components. Table 1 shows a list of the chemical elements in the plant–soil system, along with their abundances and relative neutron cross sections. In both plant and soil, hydrogen is responsible for more than 90% of the neutron attenuation.

Some hydrogen is associated with organic molecules in the system; however, most hydrogen is water borne. Plant roots may thus be distinguished from soil due to their higher water content (\(\theta\)). The gravimetric water content, \(\theta\) (g g\(^{-1}\)) of plant roots generally ranges between 0.7 and 0.95 g g\(^{-1}\), while that of soils at field capacity usually ranges between 0.12 and 0.3 g g\(^{-1}\). The structures that NR reveals in the soil–plant system are sensitive to \(\theta\).

The high neutron attenuation coefficient of hydrogen is an important advantage of NR over X rays when applied to soil–plant system because the difference in water content allows the visualization of roots. The X-ray attenuation coefficients of root and soil components are less distinct (data not shown); therefore, the resulting radiograph has less contrast. Figure 2 shows that NR provides a better contrast between roots and soil than X rays.

The attenuation coefficient (\(\Sigma\)) results from two types of neutron interactions with matter: absorption (\(\Sigma_a\)) and scattering (\(\Sigma_s\)) (Figure 3a). Hydrogen attenuates neutrons primarily by noncoherent elastic scattering.\(^\text{11}\) Neutron scattering causes deviations from the exponential law of attenuation for thicker samples (more than a few millimeters) because some neutrons are multiple scattered into the detector plane, thus producing...
Table 1  Chemical elements, listed in order of abundance, in the plant–soil system, along with their relative neutron attenuation coefficients. The plant and soil are assumed to have water contents of 0.8 and 0.2 g g\(^{-1}\), respectively.

Figure 2  Comparison of contrast between roots and soil in X-ray (120keV) radiograph (a) and neutron radiograph (b) of the same sample. While soil heterogeneity and soil cracks are more visible in the X-ray radiograph, neutron radiography provides better contrast between soil and roots.

4 CONFIGURATION OF SOIL–PLANT SYSTEM FOR OPTIMAL IMAGING WITH NEUTRON RADIOGRAPHY

A neutron radiograph is the result of all the neutron attenuation processes that occur when the neutron beam passes through a sample. The \(\Sigma\) value of the soil depends on \(\theta\) and the neutron attenuation properties of its solid components. Soils that are high in iron or organic matter...

are unsuitable for NR because their high \(\Sigma\) values obscure the visualization of plant roots. The value of \(\theta\) of the soil at the time of measurement should be as low as possible without inducing water stress in the plants. In practice, this represents the soil’s \(\theta\) at a water potential of −1 bar. Silica sands have a low inherent \(\Sigma\) and a low \(\theta\) at −1 bar. However, Menon et al.\(^{5}\) showed that the high density and sharp edges of this material perturb normal root growth. Moradi et al. (unpublished data) tested a variety of plant growth media for their suitability in NR (Table 2).

Table 2 shows that loamy sand, which permits normal root development, has a relatively low \(\Sigma\) at a \(\theta\) at a water potential of −1 bar. Loamy sand has a higher \(\theta\) at field capacity (ca. 0.35 g g\(^{-1}\)) than quartz sand (ca. 0.15 g g\(^{-1}\)). Plants can thus be left longer in loamy sand without irrigation.

Root visibility is proportional to root thickness, and inversely related to the width of the sample container.\(^{13–17}\) The minimum detectable root thickness increases exponentially as the thickness of the soil profile increases. Moradi et al. (unpublished data) showed that using the loamy sand in Table 2, with a soil \(\theta\) of 0.16 g g\(^{-1}\) (ca. −1 bar) and an average root \(\theta\) of 0.85 g g\(^{-1}\), the minimum detectable root thickness \(R\) (mm) is related empirically to the slab thickness \(T\) (mm) according to the function:

\[
R = 0.0034T^{1.68}
\]

(3)
Roots are most easily visualized in thin containers. However, this condition is not conducive to plant growth since the walls of the container restrict root development. Therefore, one needs to find a balance between the ease of root visualization and the restriction of normal plant development.

For many herbaceous species, a soil profile with a thickness of 12 mm provides enough space for relatively normal root development. This gives a minimal detectable root thickness of 0.22 mm (Equation 2). Such a setup allows the visualization of the skeleton of the root system; however, fine roots (<2 mm in diameter) are undetectable.

5 PRACTICAL CONSIDERATIONS

The sample container should be made of a material with a low $\Sigma$, such as aluminum ($\Sigma = 0.1 \, \text{cm}^{-1}$). Importantly, the system should not contain high concentrations of cobalt, which can form the persistent radioactive isotope Cobalt-60, with a half-life of about five years, upon exposure to neutron radiation.

Filling the sample container with soil as homogeneously as possible provides better contrast for root visualization. Filling from the side of the container rather than from the top results in less structural heterogeneity associated with variations in the particle size distribution and thus pore size distribution, which are visible in the resulting neutron radiograph because of variations in soil water content. Figure 4 shows the effect of filling patterns caused by pouring soil from the top of the container.

The suitability of NR to investigate root systems differs among plant species. As described earlier, thick roots with a high $\theta$ are more easily resolved than finer, drier roots. In a 10-mm-thick soil profile, the minimum detectable root size is ca. 0.16 mm (Equation 2). However, many plant species produce finer roots, which would not be visible in this system. Decreasing the thickness of the soil profile may permit the visualization of these roots, but may cause unnatural root growth patterns due to confinement. Moradi et al. (unpublished data) reported good root visibility in some members of the Fabaceae and Asteraceae families, whereas resolution was insufficient in Brassicaceae, Solonaceae, and Poaceae. In principle, larger species such as small trees could be investigated using NR. However, this would require a larger container for nonperturbed growth. Consequently, the spatial resolution would decrease and one could only resolve large structural roots.

The water content of the soil and the plant should be monitored so that the soil water content is low enough at the time of imaging to provide adequate contrast yet not so low that the plant becomes water stressed. If a series of measurements are to be taken, then one can calculate the soil $\theta$ in the zone of interest from the results of each radiograph. This requires scattering correction and a water quantification algorithm calibrated for the particular plant–soil system. Water quantification using NR has the advantage over a gravimetric measurement because it can be used to determine the water content of the soil in the zone of interest, rather than providing an average value of a soil profile that may have a heterogeneous moisture distribution.

The neutron beam formed in the collimator is not perfectly homogeneous. This also holds for the detector system. Therefore, there are spatial variations in intensity of the resulting radiography that are caused by the beam, rather than the sample. This requires that each radiograph be corrected by normalizing the image by a “flat field” or open-beam image with no sample. Similarly, noise generated by the camera assembly should be removed.

Figure 4 Soil heterogeneity resulting from filling patterns can affect the image quality. The radiographs show the roots of *Cicer arietinum* in identical soil with high heterogeneity (a) and low heterogeneity (b).
standard first step in image analysis is normalization, i.e. to transform recorded raw information relative values:

$$I' = NORM \frac{I_{raw} - I_{dark}}{I_{openbeam} - I_{dark}}$$ (4)

where $I_{raw}$ is the image as registered by the camera, $I_{dark}$ is the dark noise image without the beam, $I_{openbeam}$ contains the spatial field variation of the beam without object, and NORM is a factor to bring the resulting value into the valid range of the image-processing tools.

The background gray-level intensity within a neutron radiograph, caused, for example, by variations in the soil water content, may vary so much that a single global threshold cannot differentiate the roots satisfactorily. Menon et al.\textsuperscript{(5)} overcame this problem by modifying an algorithm originally developed for resolving blood vessels in retinal images.\textsuperscript{(18)}

### 6 APPLICATION

The application of NR can enhance the study of root development and root–soil interactions by revealing the location of roots over time without disturbance. Plant root development is a function of the plant species and the nature of the soil into which they penetrate. Soil components, such as organic matter, nutrients, and contaminants, occur heterogeneously. NR is an ideal tool to study how roots interact with patches of low or high concentration. When roots encounter a patch or discontinuity in soil, they may proliferate, wither, or continue growing unaffected. Figure 5(a) and (b) shows how NR can reveal plant responses to a patch of nickel, a toxic heavy metal, in soil. Such experiments, for example, may reveal species that avoid contaminant hotspots and reduce the risk of plant contaminant uptake. Similarly, understanding the mechanisms by which crop plants interact with patches of nutrients may aid the development of treatments to improve crop, and subsequently human, nutrition.

Perhaps more importantly, NR can quantify the spatial distribution and flux of water in the plant–soil system in near real time, in combination with root imaging. This permits the study of root water uptake and the effect of roots on the passage of water through soil. Figure 6 shows a series of images detailing water infiltration into a profile and water uptake by plant roots. Such studies have a wide variety of potential applications, such as selecting vegetation to minimize leaching from contaminated sites and the optimization of irrigation and fertilization systems.

### 7 CONCLUSIONS AND OUTLOOK

The quantification of root mass and soil water content using NR of plant–soil interactions has considerable scope for improvement, particularly, the processing of raw images obtained at the neutron facility. Refinement of root segmentation algorithms described by Menon et al.\textsuperscript{(5)} would greatly enhance the accuracy and precision of the technique. One obvious drawback of NR is that, at present, it requires access to a specialized facility, of which there are only a few available worldwide with the desirable performance. Competition for beam time is fierce, since NR finds applications in many fields of science. However, the usefulness of NR indicates that it may follow the same pattern of development as synchrotron radiation facilities. Initially, financial

The roots of *Cicer arietinum* (b) avoid the high-Ni zone, while the roots of *Berkheya coddii* (a) are unaffected. Neither plant showed any differences in the aboveground portions relative to their respective controls.
Figure 6  The change in water content (both positive and negative) of a 150 mm × 150 mm × 120 mm container, in which Lupinus albus was growing, after the infiltration of 10 mL of water ((a) 1–2 min, (b) 2–5 min, (c) 28–40 min). The wet front shows up as a dark band, while root water uptake is visible in b and c as a discontinuous gray area.

and technical constraints limited their application, but their usefulness ensured subsequent technological development and capital injection, and thus they became commonplace and the standard equipment for some analyses.

Nuclear Reaction Analysis

Guy Demortier
Facultés Universitaires Notre-Dame de la Paix, Namur, Belgium

1 INTRODUCTION: ROLE OF NUCLEAR REACTION ANALYSIS IN COMPARISON WITH OTHER ION BEAM ANALYSIS TECHNIQUES

When a material is irradiated with charged particles like protons, deuterons, \( ^\alpha \)-particles or other heavier ions, at energies ranging from a few hundred kiloelectron volts to a few megaelectron volts, the emission of photons, charged particles and neutrons gives rise to various spectroscopic methods of elemental analysis. The great majority of interactions of the incident charged particles with atoms of the irradiated material take place with atomic electrons: the incident particle progressively loses its energy (\(-dE\)) in the material. The energy loss \(dE\) is expressed by Bethe’s law of stopping power \(S(E)\)

\[
S(E) = \frac{dE}{\rho \ dx} = K \left( \frac{Z^2 m Z}{E_i A} \right) \ln \left( \frac{a E_i}{I} \right)
\]

where \(z, m \) and \(E_i\) are respectively the charge, mass and the energy of the incident particle, where \(\rho, I, Z\) and \(A\), are respectively the density, mean ionization potential, atomic number and the atomic mass of the material, and \(a\) is an adjustable parameter. \(K\) comprises only physical constants. When the incident particle has sufficient energy to ionize atoms from any shell, \(S(E)\) decreases with the increase in the incident energy (Table 1). Exceptions to this general rule occur at low incident particle energy, as seen for \(\text{He}^4\) and \(\text{He}^3\) ions in Table 1, when the projectile cannot eject inner shell electrons, the main consequence being that \(Z_{\text{eff}} < Z\). Therefore \(S(E)\), in those cases, is smaller than the expected value.

The incident particle comes to rest after crossing a distance \(R\), known as the range. This incident particle does not experience an appreciable deviation when interacting with atomic electrons. Interaction with one atomic nucleus only rarely causes deviation of the incident particle from a straight line. The range is almost the total distance that the particle travels following a straight line in the material. The range \(R\) increases with the incident projectile energy \(R \sim E^{1.3}\), and decreases with an increase in its charge and its mass. Table 2 gives some data on ranges of protons, deuterons, \(^3\text{He}\) and \(^6\text{He}\) particles \((R)\) for a selection of light, medium and high \(Z\) elements.
The width at half maximum of 27 keV (Figure 1b). The straggling gives rise to a Gaussian distribution with a non-symmetrical width. For monoenergetic protons of 1 MeV crossing a thickness of 0.2 cm, the energy loss is 4.2 keV and straggling on this energy loss has a width at half maximum of 2.7 keV (Figure 1a). For 10^{-3} g cm^{-2}, the energy loss of 1 MeV protons is 400 keV and straggling gives rise to a Gaussian distribution with a width at half maximum of 27 keV (Figure 1b). The relation between energy and depth achieved in a material is then defined in this case with an accuracy of 7%, which is relatively much lower than the inaccuracy at low incident energy: the greater the energy loss, the smaller the statistical uncertainty in the relation between depth and energy: the greater the energy loss, the smaller the statistical uncertainty in the relation between depth with respect to loss. In most practical cases achievable by NRA, the depth profiling analysis is limited to regions of a few hundred nanometers, where the Landau and Vavilov calculation theory is valid, to a few micrometers where the Gaussian profile is effective. In this last case, the straggling, \( \delta \), is simply given by Equation (2):

\[
\delta = 0.93z \sqrt{\frac{Z}{A}} \sqrt{x}
\]

where \( x \) is the depth achieved in \( \mu \text{m} \), \( z \) is the atomic number of the incident particle, \( Z \) and \( A \) are the atomic number and the atomic weight of the target, respectively. Straggling is then the same for all particles of equal \( z \) (deuteron or proton, \( \alpha \) or \( {^3}\text{He} \)). The dependence of straggling on the energy of the particle is

</table>

Note that the particle range increases with the atomic weight of the material owing to a dependence on \( Z/A \).

During this slowing down of the projectile, a statistical transfer of energy to the atomic electrons of the material takes place. This statistical behavior of the energy loss of the projectile gives rise to energy straggling: an unequal energy loss from identical particles crossing the same target material under identical conditions. The relation between the energy loss and the achieved depth is therefore subject to some inaccuracy. For a very small energy loss, straggling can be calculated using the Landau and Vavilov theory. Energy straggling is not symmetrical around the average value. For monoenergetic protons of 1 MeV crossing a thickness of 2.4 \times 10^{-5} \text{g cm}^{-2}(\approx 90 \text{nm}) of pure Al, the mean energy loss is 4.2 keV and straggling on this energy loss has a width at half maximum of 2.7 keV (Figure 1a). For 10^{-3} \text{g cm}^{-2}, the energy loss of 1 MeV protons is 400 keV and straggling gives rise to a Gaussian distribution with a width at half maximum of 27 keV (Figure 1b).

**Figure 1**  Energy straggling of 1 MeV protons for an energy loss of 4.2 keV (a) and 400 keV (b) after crossing a thickness of 2.4 x 10^{-3} g cm^{-2} (a) or 2 x 10^{-3} g cm^{-2} (b) in Al. (Adapted from G. Deconninck.\(^{(2)}\) page 72.)
to the cross-section for such elastic scattering is proportional to the stopping power of the target material. Furthermore, as took place. This depth can be determined using the depth in the material at which the scattering energy of the scattered particle at an angle close to 180° is related to the mass of the collided nucleus, Equation (3)

\[ E_{\text{scatt}} = \left( \frac{M-m}{M+m} \right)^2 E_i \]  

(3)

and to the depth in the material at which the scattering took place. This depth can be determined using the stopping power of the target material. Furthermore, as the cross-section for such elastic scattering is proportional to the \( Z^2 \) of the target atoms, RBS is particularly powerful for the study of high Z elements (see Rutherford Backscattering Spectroscopy).

The probability of coulomb excitation of a target nucleus leading to the emission of a characteristic \( \gamma \)-rays is much lower than for the backscattering and inner shell ionization phenomena. Consequently, PIGE (particle-induced \( \gamma \)-ray emission) is of particular interest for the study of light elements (see Particle-induced \( \gamma \)-Ray Emission) where PIXE and RBS suffer from a lack of sensitivity and accuracy. For these light target elements, the characteristic X-rays are of such low energy that they are absorbed into the material itself and RBS offers a much lower cross-section (because it is proportional to \( Z^2 \)). When using heavy projectiles, the forward elastic scattering of light target nuclei give rise to another method of analysis called ERD (see Elastic Recoil Detection Analysis). If the energy of the incident projectile is maintained below 5–10 MeV, no delayed radioactivity may be induced as would be the case in CPAA (charged particle activation analysis) typically performed at incident energies greater than 10 MeV (see Charged Particle Activation Analysis). By using all these analytical techniques simultaneously (or sequentially), powerful characterization of many materials may be achieved. In sections 5.3 and 5.6 of this article, we will discuss several complementary applications of nuclear reactions with other ion beam analysis (IBA) techniques.

2 FUNDAMENTALS OF NUCLEAR REACTIONS

In discussing NRA we will concentrate on prompt reactions leading to a transmutation of the target atom and then excluding RBS (see Rutherford Backscattering Spectroscopy), ERD (see Elastic Recoil Detection Analysis) and part of PIGE (see Particle-induced \( \gamma \)-Ray Emission) where the target nucleus does not change during the interaction. We will also exclude delayed \( \gamma \)-ray emission from a transmuted nucleus (see Charged Particle Activation Analysis).

The concise form of a nuclear reaction as expressed by nuclear physicists is

\[ A(a,bc)B \]

where \( A \) is the target nucleus, \( a \) the incident projectile, \( b \) (and possibly \( c \)) the emitted particles or photons, \( B \) the residual nucleus which is generally a heavy particle carrying a very low energy which remains in the target material and cannot be detected.

In this respect, a reaction named

\[ ^{27}\text{Al}(p,\gamma)^{28}\text{Si} \]

would represent the capture of a proton in an \(^{27}\text{Al} \) nucleus leading to the formation of an excited \(^{28}\text{Si} \) which immediately decays to a stable \(^{28}\text{Si} \) by the emission of a cascade of \( \gamma \)-rays. The spectroscopy of these \( \gamma \)-rays may be used as analytical signals.

The reaction

\[ ^{15}\text{N}(p,\alpha\gamma)^{12}\text{C} \]

would be induced by protons on \(^{15}\text{N} \) leading to the production of a \(^{12}\text{C} \) nucleus in an excited state after the emission of an \( \alpha \)-particle. The spectroscopy of these \( \gamma \)-rays emitted by the excited \(^{12}\text{C} \) or/and the spectroscopy of the emitted \( \alpha \)-particle could be used for analytical purposes.
The interactions of a loosely bound compound projectile (such as a deuteron) give rise to the emission of energetic protons or neutrons after stripping of the incident deuteron. The breakdown of the incident deuteron (stripping reaction) may be written as

$$^{12}\text{C}(d, p_1)^{13}\text{C} \quad \text{or} \quad ^{12}\text{C}(d, p_1)^{13}\text{C}^*$$

The former represents the stripping of an incident deuteron by a $^{12}$C nucleus, leading to the capture of a neutron in $^{12}$C to produce a $^{13}$C nucleus in its fundamental state. The emitted proton has a maximum energy $E(p_0)$. Various other ways could leave the residual nucleus of $^{13}$C in one of its $(i = 1, 2, 3, \ldots)$ excited states. The corresponding energies $E(p_i)$ of the $p_i$ protons are then lower than $E(p_0)$. The stored energy in the excited $^{13}$C nuclei will shortly afterwards appear as a cascade of characteristic $\gamma$-rays of this residual nucleus of $^{13}$C. The energy of the emitted protons $p_0, p_1, p_2, p_3, \ldots$ is quantized and the differences in their energies corresponds to the various quantum states of the residual nucleus. Several groups of protons of different energies, as well as $\gamma$-rays, may be used for analytical purposes. Stripping of a deuteron with the capture of the proton is also possible. A neutron is then emitted, but in practice the spectroscopy of these emitted neutrons is much less easy than the spectroscopy of charged particles or photons, so its use in NRA is very limited.

### 3 KINEMATICS OF NUCLEAR REACTIONS

A fundamental parameter of a nuclear reaction is the $Q$ value. It represents the balance between the total rest mass of interacting particles and those of emitted ones. Equation (4):

$$Q = (m_A + m_a - m_B - m_b)c^2$$

where $c$ is the velocity of light in vacuum. A positive $Q$ value is a characteristic of a nuclear reaction in which some mass is converted into kinetic energy of emitted particles. This $Q$ value added to the incident particle energy $E_a$ is shared by both outgoing particles B and b, Equation (5):

$$Q = E_b + E_B - E_a$$

The partition between $E_B$ and $E_b$ may be calculated by using conservation laws: conservation of total momentum because the interaction takes place without any influence of external forces; conservation of total mass–energy because the isolated system formed by the incident particle and the target nucleus is being considered. In terms of $E_a$ and $E_b$, one finds Equation (6):

$$Q = E_b \ 1 + \frac{m_b}{m_B} - E_a \ 1 - \frac{m_a}{m_B}$$

$$- \frac{2}{m_B} [E_aE_bm_am_b]^{1/2} \cos \theta$$

When $b$ is the lightest emitted particle, its energy $E_b$ in the direction $\theta$ relative to the incident beam of particles $a$ is given by Equation (7):

$$E_b^{1/2} = \frac{\cos \theta (m_am_bE_a)^{1/2} \pm (m_am_bE_a \cos^2 \theta)}{m_B + m_b}$$

As $E_b^{1/2}$ must be a positive quantity, the plus sign must only be kept if the following condition is met:

$$(m_B + m_b)m_BQ + (m_B - m_a)E_a | \geq 0$$

This is always the case for positive $Q$ values. For negative $Q$ values, the minimum $E_a$ energy giving rise to the emission of $b$ at $\theta = 0^\circ$ is given by Equation (8):

$$E_{a\min} = \|Q\| \frac{m_B + m_b}{m_B + m_B - m_a}$$

For higher $E_a$ energies, two different energies may be attributed to the same particle b emitted at the same angle $\theta$ but in a limited energy range of $E_a$ and only for the ejection of $b$ in the forward direction. We will ignore this special behavior which could be inconvenient for elemental analysis.

A list of selected reactions for the study of light isotopes $(A \leq 20)$ is given in Table 3. Resonant reactions which may be used for depth profiling (see sections 5.1 and 5.2 below) are particularly interesting and a suggestion for the best $E_a$ incident energies is given.

For hydrogen, helium and lithium isotopes in a material, the detection of coincidental b and B particles may sometimes be used to solve chemical interference problems (superposition of signals from particles emitted with the same energy but arising from different B nuclei). As $E_b$ energies are also dependent on the emission angle $\theta$, a specific geometrical assembly may be required for solving interference problems.

The geometry of a nuclear reaction used for analysis in thick target materials is given in Figure 2. The incident particle “a” hits the sample at point I, crosses a thickness $x/cos \alpha_a$, losing some of its energy (mainly by interaction with atomic shell electrons) and induces a nuclear reaction at P. The emitted particle with an energy $E_b(\theta)$ to be calculated for $E_a = E_a(0) - \Delta E(x/cos \alpha_a)$ is produced at P and has to cross the distance $x/cos \alpha_a$ before emerging from the sample surface at O. The outgoing energy at O is equal to $E_b(\theta) - \Delta E_b (x/cos \alpha_a)$.

\(a\) For applications of these nuclear reactions to elemental analysis see Demortier.\(^60\)

The angle \(\theta\) is simply \(\alpha_i + \alpha_o\). As the most intense fraction of the emitted particles are elastically scattered \(\alpha\) particles, some calibrated absorber has to be inserted between the surface sample and the detector in order to stop them all and then to accept only \(\beta\) particles induced by a true nuclear reaction, when the target nucleus \(A\) is transmuted to another one, \(B\). Reactions with large \(Q\) values and detection of \(\beta\) particles of mass lower than the mass of \(\alpha\) are particularly useful characteristics of nuclear reactions suitable for analysis. A thin absorber will stop all the scattered \(\alpha\) particles but will not greatly affect the energy of the lighter emitted \(\beta\) particles (see Equation 1).

In special cases corresponding to a large \(Q\) value and a low \(E_\alpha\) energy, one may expect to detect \(\beta\) particles selectively with a higher mass than the incident particle even after crossing the dedicated absorber. Reactions \(^6Li(d,a)^4He\), \(^7Li(p,a)^4He\), \(^9Be(^3He,a)^8Be\), \(^10B(d,a)^8Be\),
**NUCLEAR REACTION ANALYSIS**

**Figure 2** Parameters involved in the study of thick materials by the nuclear reaction $A(a, b)B$.

$^{14}\text{N}(d,\alpha)^{12}\text{C},$ and $^{19}\text{F}(p,\alpha)^{16}\text{O}$ shown in Table 3 would offer this possibility for an incident $E_a$ energy in the region of 1 MeV, as would $^{11}\text{B}(p,\alpha)^{8}\text{Be},^{18}\text{O}(p,\alpha)^{15}\text{N},^{19}\text{F}(p,\alpha)^{16}\text{O}$, when using incident protons in the range of a few hundred kiloelectron volts.

The energetic scale of the compound nucleus $C^*$ made up with all the nucleons of $A$ and $a$ (and then also $B$ and $b$) may be represented schematically (Figure 3).

Quantum states have their own energy width $\Gamma = \Delta E$ (and their associated lifetime $\Delta T$ related by $\Gamma \Delta T \geq \hbar$).

Low-lying states (bound states) can only decay through $\gamma$-ray emissions: their width is of the order of $10^{-3}$ eV. At much higher excitation energies, known as positive energy states, the width is typically of the order of 0.1–100 keV. These levels may be formed by several typical configurations of nucleons, in particular $(A + a)$, $(B + b)$ or $(C_\gamma)$. Each of these configurations is associated with a typical width $\Gamma_a$, $\Gamma_b$, $\Gamma_\gamma$. The sum of all possible configurations $\Gamma_i$ is related to the total width $\Gamma$: the higher $\Gamma$, the shorter the lifetime of the level.

When the incident particle $a$ is sent on the nucleus $A$ with a precise energy $E_{ar}$, the probability of forming an excited nucleus is greater than for any other $E_a$ energy slightly greater or lower than $E_{ar}$. For particles of energy $E_{ar}$, the probability of the emission of a particle $b$ (and/or a cascade of characteristic $\gamma$-rays) is also enhanced.

Owing to competing phase shifts in the quantum mechanical behavior of nuclear reactions, the cross-section may sometimes be very low in the vicinity of a resonant energy. The discontinuities in the cross-section values of nuclear reactions induced by $a$ on $A$ give rise to some potential for depth profiling of $A$ nuclei: signals induced in the detector by $b$ or $c$ particles will be particularly intense when arising from those regions in the target material where $E_a = E_{ar}$. If a material is irradiated with particles $a$ of energy greater than $E_{ar}$, the region where $E_a$ will reach this particular energy $E_{ar}$ will be achieved at a defined depth below the surface. This depth may be calculated by using the $S(E_a)$ values of

**Figure 3** Mass–energy scheme of a resonant nuclear reaction. The formation in various levels of an excited compound nucleus (CN) $b$ by the interaction of an incident particle $a$ on a target nucleus $A$ takes place only for discrete incident $E_a$ energies ($E_a^*$ calculated in the center of mass system). Particles $b$ of various energies ($b_0$, $b_1$, …) are consequently emitted to give rise to a final nucleus $B$ which could appear in various states (c). (From G. Deconninck, LARN [2])
Table 1 and the corresponding detected \( E_b \) values may be calculated by using Equation (7) and the necessary correction for the energy loss in the outgoing direction (see Figure 2) which is to be calculated by using the corresponding \( S(E_b) \) values of Table 1.

The depth resolution is directly related to the total width of the resonance: the narrower the resonance, the more precise will be the depth resolution. Useful resonant energies \( E_{at} \) for depth profiling are limited for several reasons:

1. The cross-section at the resonant energy must be intense in comparison with its value outside the resonance.
2. The resonant energy must be well isolated in order to avoid superposition of signals originating from various regions below the sample surface where several resonant energies may be reached.
3. The resonance width must be of the order of (or less than) the energy resolution of the whole experimental set-up (taking into account the accelerator energy resolution, detector resolution, detector solid angle accepting particles emitted with various \( \theta \) and then various energies . . .).
4. The energy straggling of the incident particles into a buried layer under the surface must be sufficiently small, as should be the energy straggling of the emitted particles along its outgoing path and into the necessary absorber (inserted between the target and the detector to stop elastically scattered particles).

The detection of emitted \( \gamma \)-rays from the residual nucleus does not suffer from the last uncertainty (straggling in energy of the emitted particle) but \( \gamma \)-rays may be affected by Doppler shift when the emitting residual nucleus decays before being stopped in the material. Doppler broadening of emitted \( \gamma \)-rays only arises if the lifetime of the recoiling \( C^0 \) or \( B^* \) nuclei is shorter than the time required to stop this recoil nucleus in the sample target.

4 IDENTIFICATION OF SIGNALS FOR ANALYTICAL PURPOSES

Modern particle detectors of protons, deuterons, \( ^3 \)He and \( \alpha \)-particles with energies in the megaelectron volt range are now exclusively solid-state detectors: p–n junctions made with crystals of silicon\(^{(7)} \)

The full energy of the detected particle is converted into pairs of electrons and holes: the number of pairs is strictly proportional to the deposited energy. A reverse polarization of the p–n junction is maintained by an adjustable bias across the desired detector depth, which is at least the range of the particles of maximum energy to be detected. This range may vary from 5\( \mu \)m for 1-MeV \( \alpha \)-particles to 0.6 mm for 7-MeV protons. The energy resolution (width at half maximum of a peak induced by monoenergetic particles) is generally in the order of 8–15 keV for the whole range of these useful energies.

For the highest energies, a succession of detectors mounted as a telescope may be necessary. The associated electronics of these telescopes is tailored in order to collect all the signals induced in the successive detectors coincidentally. For energetic particles, the time delay between the signals produced in two distant thin detectors can be taken into account by measuring the time between the two short signals; in this last case, the time-of-flight of the particle is used. For distant detectors, this time interval is used to identify the mass of the particle only. A third detector, or a set of successive detectors which stop the particle completely, is necessary to determine the energy of the charged particle. The resolution of time-of-flight systems is indeed insufficient to measure the energy of the energetic \( \beta \) particles accurately.

The kinetic energy (converted into a proportional signal in the solid-state detector and possibly the time-of-flight) is a characteristic quantity which allows experimentalists to identify the nucleus which was participating in the nuclear reaction. If this nuclear reaction took place at the surface of the sample and if the emitted particle were directly collected in the backward direction, the energy of this detected particle would be simply given by Equation (7), where \( E_a \) is the incident energy delivered by the particle accelerator. In contrast if the reaction took place below the surface, the incident particle reaches this region with a lower energy \( E'_a < E_a \). \( E'_a \) can be calculated by using the target stopping power along the entrance pathlength \( x/\cos \alpha_o \) which can also be calculated using the appropriate stopping power of the material for this particle \( b \). Dividing the whole distribution of signals from \( E_{b_{\text{max}}} \) to \( E_{b_{\text{min}}} \) into energy intervals with a width of the order of the energy resolution of the experimental set-up (including energy straggling for both incident and emitted particles), it is possible to determine the depth profile of thicknesses ranging from 10 nm to a few microns. The experimentalist must have the ability to certify the origin of signals and to exclude eventual interfering elements (see Figure 4).

Figure 4 shows that particles with identical energies may be emitted with the same incident energy \( E_o \) and at the same angle \( \theta \) by two different A nuclei. Changing
the energy $E_a$ or the angle of detection are alternatives that may be used to deal with the interferences. It may be helpful to use two detectors at two different angles simultaneously for complicated analyses: interferences between reactions at two different A nuclei do not take place at both angles (see Figure 4a and b).

In addition to the measurement of the energy of $b$ particles which identify the target nuclei, the measurement of the intensity of signals with identical energies gives the concentration of these nuclei of interest. The intensity of such signals is governed by the cross-section of the particular nuclear reaction: the greater the cross-section, the better the capability of the nuclear reaction to perform accurate (due to statistics) and sensitive elemental determinations. Knowledge of all characteristics of the nuclear reaction (presence of resonances, angular distributions of emitted particles and elimination of interfering reactions by selecting the best angle of detection) is of prime importance to achieving confident analyses.

All these data may be found in various nuclear data tables\cite{42-45} and handbooks.\cite{46,47}

For $\gamma$-ray detection, large volume (40–100 cm$^3$) Ge(Li) photon detectors of high energy resolution (1.2 keV at 1.5 MeV) are used. They are cooled at liquid nitrogen temperature. Various processes of interaction (photoelectric effect, Compton effect, pair creations) give rise to an extended spectrum from which only the full

**Figure 4** (a) Relation between the energy $E_b$ of emitted $\alpha$-particles at $\theta = 90^\circ$ and the incident energy $E_a$ for the most useful nuclear reactions induced by protons on $^6$Li(a), $^7$Li(b), $^9$Be(c), $^{10}$B(d), $^{11}$B(e), $^{15}$N(f), $^{19}$O(g), $^{19}$F(h), $^{23}$Na(i), $^{27}$Al(j) and $^{31}$P(k). Figure 5 High-energy part of a γ-ray spectrum obtained with a solid-state Ge(Li) detector during the irradiation of a material containing fluorine. The γ₁, γ₂ and γ₃ peaks are produced by (p, αγ) reaction leading to excited ¹⁶O. Both γ₁ and γ₂ peaks are broadened by the Doppler effect because of the short lifetime of the corresponding levels of the oxygen nucleus which decays before being at rest in the material. The sharp γ₃ peaks do not suffer this broadening. Each characteristic γ-ray gives rise to signals in three regions: the full energy peak and two escape peaks corresponding to the loss of one or two of the annihilation photons (511 keV) produced after the initial pair creation. (From G. Deconninck, LARN.²⁹)

energy peak is selected for γ-ray identification. The efficiency of such a detector is quite high for γ-rays of 2 MeV or less but may also be used at higher energies (Figure 5).

An alternative would be a large NaI or BGO (bismuth germanate oxide) detector (about 1000 cm³) with a very high detection efficiency but with a much lower energy resolution. This kind of detector is particularly useful for depth profiling using (p,γ) or (p,αγ) resonant reactions involving γ-ray energies of more than 2 MeV. In contrast to particle spectroscopy whose energy is a complicated function depending on Eₐ, θ, x/ cos α₁ and x/ cos α₂, γ-ray spectroscopy only concerns measurement of the energy of the excited state of the promptly decaying excited B* nucleus. To profile one element which could give rise to a resonant nuclear reaction (see Table 3) at a particular Eₐ energy, the Eₐ energy is progressively increased to allow this resonant reaction to take place at various depths below the surface. For increasing values of (Eₐ - Eₐₑ) the resonant reaction would produce γ-rays at depths calculated using the stopping power (Table 1) of the incident particle a only.

Examples of depth profiling using γ-ray or particle spectroscopy will be given in sections 5.1 and 5.6 of this article.

The analytical investigation of large specimens or fragile materials which cannot be introduced in the vacuum sometimes requires the use of external beam geometry. This technique is now widely familiar to PIXE (see PIXE (Particle-induced X-ray Emission)) and PIGE users (see Particle-induced γ-Ray Emission) but may be also tailored for NRA when the outgoing particle has a sufficiently high energy (i.e. for (d,p) reactions) by comparison with the energy of the incident particle. The incident beam crosses a thin foil of metal or of mylar before reaching the sample situated outside the vacuum vessel of the accelerator. The distance in the air between the target and the detector may be finely tuned in order to stop the elastically backscattered α particles completely and allow only b particles to reach this detector. The energy straggling of this incident particle in the exit window and in the air, and the energy straggling of the emitted particle in the sample and also in the air does not allow, in this particular case, depth profiling to be performed.
5 EXAMPLES OF APPLICATION

Many laboratories in the world use NRA in the field of materials science. We have selected a few typical results. The first concerns the study of hydrogen distribution in the depth of materials by using a methodology involving the detection of \( \gamma \)-rays produced by irradiation of energetic \(^{15}\)N ions to induce a resonant nuclear reaction at various depths in the sample. General problems related to energy straggling, cross-sections and performances of \( \gamma \)-ray detectors will be discussed.

The second results concern the depth profiling of F and Na in \( \text{SnO}_2 \) coated glass (an insulating material) using simultaneous RBS and NRA techniques at two particular resonant proton energies for \((p,\alpha\gamma)\) reactions. The third application benefits from simultaneous PIXE and NRA for a complete characterization of all the components of a \( \text{YBaCuO} \) superconductor using a microbeam of low energy deuterons.

We will then present the use of a \((d,p)\) reaction for the study of microregions in the grain boundaries of Au-Si alloys and for the determination of traces of sulfur in ancient gold jewellery artefacts. Nuclear reactions are indeed not sensitive to high \( Z \) nuclei owing to the high coulomb barrier, but they offer a unique technique (free of interference) for studying light elements in heavy matrices. The last application concerns the determination of all the major and minor elements and a majority of trace elements (in the region of a few micrograms per gram) in a reference material of biological interest.

5.1 Analysis of Hydrogen in Various Materials

The use of megaelectron volt ion beams to analyze materials for hydrogen has been more interesting and more important than even the early researchers in this field realized. The reasons for this are simple:

1. Hydrogen is probably the most common contaminant element, especially in thin film materials.
2. Hydrogen has important effects on the chemical, physical and electrical properties of many materials.

The analysis for hydrogen is difficult or impossible by most traditional analytical methods.

Megaelectron volt ion beams to probe for hydrogen may be used in two different approaches. The first is NRA, in which megaelectron volt ions bombard a sample, inducing nuclear reactions between the incident ion and hydrogen in the target. The second is ERD in which megaelectron volt ions bombard a sample and through elastic collisions cause hydrogen ions to recoil out of the sample with the number of these recoils used to determine the amount of hydrogen in the target. This last problem (of ERD) is treated in Elastic Recoil Detection Analysis. The basic principle for hydrogen analysis using NRA is to use nuclear reactions between protons and light nuclei but in the reverse direction: light nuclei are incident particles and hydrogen is the collided nucleus.

While many nuclear reactions are possible for hydrogen analysis, the reactions most commonly used to probe for \(^1\)H in material are those induced by \(^{15}\)N and \(^{19}\)F. These reactions are similar in many ways: they both have low-energy isolated resonances above a few megaelectron volts. Another reaction which is capable of profiling much deeper into samples uses a \(^{7}\)Li beam. The important parameters for most useful reactions for H analysis are given in Table 4.

</tbody>
</table>

The very narrow and intense resonance is shown in Figure 6. The \( \gamma \)-ray intensity at the resonant energy is four orders of magnitude higher than the one off-resonance. A beam of \(^{15}\)N ions is incident on the sample being analyzed and the yield of characteristic \( \gamma \)-rays of \(^{13}\)C is measured. Because this is a resonant reaction, the cross-section is large at the resonance energy \( (E_{\text{res}}) \) and small off-resonance. Therefore, if a sample is bombarded with \(^{15}\)N ions at the resonance energy, the yield of \( \gamma \)-rays is proportional to the hydrogen only present at the surface.
Figure 6 Variation of the cross-section of the reaction \( H(\text{^{15}N},\text{ag})\text{^{12}C} \) for increasing \( \text{^{15}N} \) incident ions. The cross-section increases by at least four orders of magnitude at the resonance energy \( (E_i = 6.385 \text{ MeV}) \). (Data are taken from Horn and Lanford.)

of the sample. If the beam energy is raised above the resonant energy, there is no longer a reaction with surface hydrogen (because the \(^{15}\text{N} \) ions are above the resonant energy) but as the ions lose energy when penetrating the sample, they reach the resonant energy at a particular depth: the yield of \( \gamma \)-rays is then proportional to the hydrogen content at this depth.

Characteristic \( \gamma \)-rays from the reaction are detected by a large (and therefore efficient) scintillation detector (NaI), or a BGO detector, located close behind the irradiated samples.

The \( \gamma \)-ray yield is proportional to the energy integrated area under the Breit–Wigner formulae for a resonant cross-section, i.e. proportional to \( \sigma_0 \Gamma \), where \( \sigma_0 \) is the cross-section at the resonance energy and \( \Gamma \) is the width of the resonance. The yield of \( \gamma \)-rays is also inversely proportional to the energy loss of the incident ions. This is because the yield of \( \gamma \)-rays is proportional to the amount of H per cubic centimeter within the resonance detection window (i.e. when the energy is on-resonance) and this is proportional to the thickness of the resonance detection window. This thickness is inversely proportional to \( dE/dx \).

As in all resonant nuclear reaction profiling, a measurement of the number of \( \gamma \)-ray signals induced by the nuclear reactions versus incident energy is made. A known standard material containing a known quantity of hydrogen at a well-defined depth is used for quantitative determination of depth profiles in the material to be studied.

The matrix of this reference material may be different from the matrix of the material under investigation. All the matrix effects are contained in \( dE/dx \) which is matrix-dependent.

The depth resolution \( (\Delta x) \) of the method depends on the measured full width at half maximum (fwhm) of the hydrogen profile, for an infinitely thin layer of hydrogen at a certain depth in the sample. This is then determined by the width of the reaction resonance \( (\Gamma) \) and the fluctuations in the energy \( (\Delta E) \) of the bombarding ions at this depth in the sample. \( \Delta E \) has contributions from the energy spread in the incident proton beam \( (\Delta E_b) \), which depends on the performance of the accelerator, energy straggle \( (\Delta E_s) \) (see Equation 2) and, for detection of \( \gamma \)-rays, the Doppler energy broadening \( (\Delta E_D) \). Since in most cases these are all Gaussian distributions, the total energy width is obtained by adding them in quadrature, Equation (9):

\[
\Delta E^2 = \Delta E_b^2 + \Delta E_s^2 + \Delta E_D^2
\]  

For the depth profile at the extreme surface, the energy straggling is not Gaussian and another more sophisticated procedure is involved. Some additional explanation is given for Doppler effect. Hydrogen atoms in materials are not stationary but vibrate. For a narrow nuclear resonance, this motion can shift the reaction on- and off-resonance. For example, the width of the \(^{15}\text{N} \) resonance is 1.8 keV, whereas the Doppler broadening is in the range 5–15 keV, depending on the strength of the hydrogen bond. This contribution is nevertheless usually small compared to straggle, except when analyzing very thin hydrogen surface layers where the Doppler effect is the dominant source of broadening.
The ideal nuclear reaction for profiling would be one with an infinitely narrow resonance reaction with a zero cross-section off-resonance. The $^{15}$N nuclear reaction is nearly this ideal. The off-resonance cross-section is more than four orders of magnitude smaller than the peak resonance cross-section. For other resonance reactions, the off-resonance cross-sections are generally much larger.

However, even in this favorable case, there are situations where the nonzero off-resonance cross-section needs to be taken into account. Thus, a layer of TiH$_2$ on clean Si was profiled.$^{(51)}$ The results of this profile are shown in Figure 7. The counts above 7.2 MeV essentially all come from the off-resonance cross-section.

The correction for such off-resonance effects is simple. Since the off-resonance yield is proportional to the on-resonance energy $\gamma$-ray yield (integrated between 6.4 and 7.2 MeV in Figure 6) times the off-resonance cross-section, once the proportionality constant is known, these off-resonance counts are subtracted from the total counts. In the case of $^{15}$N NRA, this correction is

$$Y_{\text{off res}} = (1.28 \times 10^{-5}) I$$

where $I$ is the energy integrated on-resonance yield (in counts keV)$^{(51)}$.

This correction is simply due to the fact that no other resonance at higher energy (the next one being at $E_{\text{inc}} = 18$ MeV) in the $^{15}$N + p reaction gives a contribution.

The problem of sensitivity or limit of detection is discussed now. When making NRA measurements where the reaction product is a high-energy $\gamma$-ray, the detectors are also sensitive to background radiations, such as cosmic rays and, in some cases, accelerator-generated radiation. This background is the main factor in the limitation of the sensitivity of NRA. There are several ways in which sensitivity can be improved, the first being by high beam current. Since the external background is independent of the beam current whereas the real count rate increases linearly with this beam current, sensitivity improves linearly with beam current. However, this approach can be used only up to the limit of the beam current available in a particular accelerator or the limit of beam current

![Figure 7](image-url)
that a particular sample will withstand. The last limitation may be avoided by rastering the beam along a large area on the surface for samples where the surface homogeneity is guaranteed.

Another approach is to build material and electronic shields to reduce the background in the γ-ray detectors. This approach is now much easier with the advent of bismuth germinate BGO scintillation detectors which are progressively replacing the usual NaI scintillator. BGO detectors are much more efficient (for a given size) than NaI and are much less sensitive to neutrons generated by cosmic rays.

In good cases, sensitivities of the order of micrograms per gram and depth resolutions of a few nanometers are possible. However, the practical limit achievable is dependent on the nature of the sample being analyzed and on the quality of the accelerator (energy resolution, beam current intensity, etc.) and its associated equipment.

Historically, NRA has been used in many studies of hydrogen in materials. However, because of the wide availability of new facilities for He ERD and because of the potential of high-energy heavy ion ERD, this alternative method is becoming more popular (see Elastic Recoil Detection Analysis).

Nuclear reactions may also be used for the study of the other isotopes of hydrogen. Some of the reactions that have been used include: \(^2\mathrm{H}(d,p)\mathrm{T}\), \(^2\mathrm{H}(d,n)\mathrm{He}\), \(^3\mathrm{He}(d,p)\mathrm{He}\), \(^3\mathrm{H}(d,n)\mathrm{He}\) and \(^3\mathrm{H}(p,n)\mathrm{He}\). For all reactions giving rise to neutrons, the analytical technique involves the detection of the associated charged particle.

The most widely used reaction for deuterium analysis is the \(\mathrm{D}(\mathrm{d},p)\mathrm{T}\) reaction which has a positive \(Q\)-value (18.35 MeV) making identification of the reaction products easy and the elimination of interfering signals comfortable using a coincidence technique with the detection of both particles simultaneously emitted: \(p\) and \(\mathrm{He}\). Depth information is obtained by the energy loss of the outgoing \(\mathrm{He}\) particles. The cross-section for this reaction is not large (70 mb at 0.75 MeV) compared to the elastic cross-section (see Elastic Recoil Detection Analysis), so count rate problems are of concern.

### 5.2 Depth Profiles of F, Na in SnO\(_2\) Coated Glass

A typical application of simultaneous RBS and resonant NRA is the study of fluorine and sodium migration in a SnO\(_2\) layer deposited on a glass substrate. The depth profiles are measured by proton-induced resonant reactions. The depth calibration which is essential to localize the interface is done by proton backscattering on Sn. As the SnO\(_2\) layer is thin (200 nm), the same stopping power may be used for incoming protons and outgoing elastically scattered protons on Sn, the heaviest element in the sample. The fwhm of the Sn signals is therefore twice the actual energy loss (\(\Delta E_p\)) of the incoming protons in the SnO\(_2\) layer. \(\Delta E_p\) then gives the exact position of the interface of SnO\(_2\) with the bulk glass in terms of energy, without using the stopping power parameters. RBS is therefore used to calibrate the resonant reaction excitation curves.

Profiling of sodium is carried out by using the \(^23\mathrm{Na}(p,\gamma)\mathrm{Ne}\) at the resonance energy \(E_R = 1010.5\) keV (resonance width \(\Gamma_R < 0.5\) keV). \(\gamma\)-Rays of 1634 keV are detected in a 4 in \(\times\) 4 in NaI detector offering maximum efficiency. The target sample is irradiated into the well of the NaI detector. As it is essential to reduce the irradiation duration to prevent sodium migration induced by the beam, the beam is rastered on the sample in order to avoid local overheating of the glass. The experimental excitation curve is displayed in Figure 8(b). A small surface concentration is observed followed by a steep edge at \(E_p = E_R + 14.6\) keV, and then a constant concentration of 16 atom% (the bulk concentration of Na in glass). The RBS spectrum was collected simultaneously. Figure 8(a) shows this RBS spectrum for the SnO\(_2\) layer on glass under the same experimental conditions as used for the profiling, i.e. \(E_p = 1.015\) MeV. The width \(2\Delta E_p\) of the Sn signal as measured on the RBS spectrum is 29.2 keV (twice 14.6 keV) and can be related directly to the step in the Na depth profile. The exact localization of the concentration step with respect to the interface is therefore known directly, without any calculation using physical parameters such as the stopping power of the Sn and O mixture. Therefore, any other element that could be present in the layer and whose measurement is not accessible by either RBS or NRA methods will not disturb the measurement.

Profiling of fluorine is done using the \(^19\mathrm{F}(p,\gamma)\mathrm{O}\) at resonance energy \(E_{\gamma} = 340\) keV (\(\Gamma_R = 2.4\) keV). The \(\gamma\)-rays in the range of 6–8 MeV are also detected using the large NaI scintillator. The excitation curve is displayed in Figure 8(d) showing a shallow concentration followed by a huge peak localized in the SnO\(_2\) layer, close to the interface with the glass substrate, and just in front of the sodium step. The energy loss \(\Delta E_p\) corresponding to the interface was, once again, measured by the backscattering spectrum which was collected simultaneously in the same way as in Figure 8(c). Once more, the width of the Sn peak is twice the energy loss of the protons measured by the new RBS spectrum. Using these two resonant nuclear reactions, it was then possible to localize the relative position of (i) the fluoride layer (completely in the SnO\(_2\) surface layer), (ii) the interface between SnO\(_2\) and the glass, and (iii) the sodium step which is located entirely in the glass substrate.
5.3 Stoichiometry of Y−Ba−Cu−O Superconductors

In addition to crystallographic characterization and measurement of thermal and electrical properties of superconducting materials, rapid and nondestructive analytical techniques involving milliprobe facilities were developed to search for the best conditions for their synthesis and to test the stoichiometric composition of $\text{YBa}_2\text{Cu}_3\text{O}_{6+\delta}$.

Irradiation of pellets made from a powder superconductor with 2 MeV deuterons may give, at the same time, the relative bulk concentration of all the elements.$^{(55)}$ A beam of deuterons is focused on a narrow region (5 µm) of the pellet. A solid-state particle detector, situated at 135° relative to the incident beam, collects protons from (d,p) reactions on O and C. A low carbon content is always possible from the precursors used in the synthesis ($\text{BaCO}_3$) or from a deposit on the sample surface by the incident deuteron beam of some residual atoms from oil used in the pumping set-up. The elastically scattered deuterons are stopped in a mylar foil of appropriate thickness inserted between the irradiated surface and the detector. Simultaneously, a Si(Li) detector collects X-rays, L X-rays of Ba and K X-rays of Cu and Y which are used as analytical signals for the rest of the elements. A second solid-state detector is installed at 170° relative to the incident beam and is used to collect the elastically backscattered deuterons in order to check the homogeneity of the Y, Ba and Cu distribution at depth. A flat plateau of Ba, Y and Cu in the RBS spectrum would certify this homogeneity. The deuteron beam is rastered on the surface. The integrated time of the whole measurement is of the order of 1 h to create a map of the four elements in an area of $40 \times 40$ spots of 5 µm wide.
A typical proton spectrum is shown in Figure 9(a). Carbon signals from surface contamination appear in region D. Carbon signals from the bulk material (region C) are to be subtracted from regions of oxygen signals (regions A and B). The subtraction of the carbon contribution in regions A and B of oxygen in the bulk (A) and at the surface (B) is performed by calculating the relative contribution of carbon in (C) and in the corresponding regions A and B of the proton spectrum collected on a pure carbon homogeneous standard sample (Figure 9b).

Using the pure RBS cross-section on Cu, Y and Ba, the stoichiometric determination of heavy compounds (expected to be $Y_1Ba_2Cu_3$) was $Y_1Ba_2Cu_3:01$ (Ba$_2$ as reference).

The accuracy of the measurement of O concentration ($7 \pm 1$) by RBS was not sufficient because of superposition of the O signals on to the huge contribution of the heavier elements. The accuracy of the O content using results of the (d,p) reaction, is of the order of 3% (statistical accuracy).

![Figure 9 Proton spectra from (d,p) reactions on C and O. The incident deuteron energy is 2 MeV and the mylar absorber thickness is 10 mg cm$^{-2}$. Oxygen may be profiled down to 5–6 mg cm$^{-2}$ below the surface. (Reprinted from G. Demortier et al., 'Stoichiometric Characterization of Y–Ba–Cu–O Superconductors With Nuclear Probes', Nucl. Instrum. Methods Phys. Res., Sect. B, 30, 491–496, Copyright (1988), with permission from Elsevier Science.)](image_url)

Materials showing the strongest Meissner effect (levitation of a small magnet) at liquid nitrogen temperature are also those showing the best homogeneity in Cu, Ba and Y concentrations in 5 × 5 × 5 µm regions analyzed (Figure 10a and b). Possible local nonhomogeneities in several samples show that Ba and Y are related.$^{[56]}$

Ternary diagrams of three of the four components (Y, Ba, Cu, O) indicate that, as far as the most homogeneous material is concerned, local discrepancies from the ideal $Y_1Ba_2Cu_3$ composition are mainly observed in the Y content, the reason lies only in the poor statistical accuracy on K X-rays of Y induced by 2 MeV deuterons.$^{[56]}$ An improvement in the accuracy of Y determination is achieved when the same sample is studied by PIXE induced by 3 MeV protons. The distribution of the points in a ternary diagram involving O, Cu and Ba as extracted from numerical results on the homogeneous material (Figure 11a) is not of statistical origin, but indicates some nonhomogeneity in the microscopic distribution of oxygen. For the second (nonhomogeneous) sample, the nonhomogeneity is so great that the points are scattered far from the ideal position: the center of the triangle. Nonhomogeneities in the O concentration of Figure 11(b) cannot be correlated with the presence of any specific oxide (CuO, Y$_2$O$_3$, BaO, etc.). For the homogeneous sample, the local concentration of oxygen exhibits variations of about 10% around the expected value of 6.7. The reason could be the presence, in the synthesized sample, of copper in two different valence states ($2^+$ and $3^+$).

The experimental accuracy on the relative concentrations of Cu, Ba and O, using simultaneously PIXE and (d,p) reactions, was less than 3%.

### 5.4 Three-dimensional Microanalysis of a Gold–Silicon Eutectic Alloy

A film of silicon was deposited on pure polycrystalline gold foils, previously rolled down to thicknesses ranging from 10 to 20 µm. The deposition was performed with an electron gun at low pressure. The amount of evaporated silicon was adjusted in order to obtain films up to 1 µm thick on the gold substrate. This substrate was maintained at 400 °C during the silicon deposition, a temperature which is slightly higher than the eutectic temperature (363 °C). At this temperature a liquid Au–Si mixture diffuses, during the deposition procedure, in the gold foils (Figure 12) but only along well-defined paths, the gold grain boundaries. K X-rays of Si induced by PIXE (Particle-induced X-ray Emission) clearly indicate that a gold–silicon alloy has diffused on the surface of the foil by forming characteristic leaf-shaped decorations starting from the boundaries of the gold grains which were flattened by the rolling procedure. Several of these
Figure 10 Concentration maps of Ba, Cu, Y and O in bulk superconductors. Concentrations are presented by 64 gradations of gray. The maximum values are, respectively, in each pixel: 8192 for Ba(L), 4096 for Cu(Kα), 256 for Y(Kα) and 1024 for O (protons). The beam diameter is less than 5 µm and the distance between steps is 10 µm. (a) Homogeneous YBaCuO sample; (b) Nonhomogeneous YBaCuO sample. (Reprinted from G. Demortier et al., ‘Stoichiometric Characterization of Y–Ba–Cu–O Superconductors With Nuclear Probes’, Nucl. Instrum. Methods Phys. Res., Sect. B, 30, 491–496. Copyright (1988), with permission from Elsevier Science.)

Figure 11 Ternary diagram of Cu, Ba and O for a homogeneous sample (a) and a nonhomogeneous one (b). (Reprinted from G. Demortier et al., ‘Stoichiometric Characterization of Y–Ba–Cu–O Superconductors With Nuclear Probes’, Nucl. Instrum. Methods Phys. Res., Sect. B, 30, 491–496. flattened grains may occupy the whole thickness of the foil. Therefore, the diffusion of the liquid phase took place through the whole gold foil thickness. The diffusion is so fast (a few minutes at such a low temperature cannot be explained by a process of solid state diffusion) that nothing other than a liquid phase of gold–silicon eutectic alloy could diffuse. The atomic concentration of Si in this eutectic alloy is 19% (about 3.2% Si by weight).

The depth profile of Si in gold is taken using a (d,p) reaction.57 The nuclear reaction 28Si(d,p0)29Si (Q = 6.25 keV) (leaving the residual 29Si nuclei in their fundamental energy level) is mainly governed by neutron capture involving no exchange of angular momentum (ơ = 0). As a consequence, the maximum intensity of the proton emission is achieved in the forward direction. The cross-section at θ = 0° of this nuclear reaction at E_d = 2.8 MeV is quite large at 6 mb sr⁻¹. We then chose to detect the emitted protons in the forward direction. In this special arrangement, the proton detector is situated into the incident deuteron beam (Figure 13). As incident deuterons of 2.8 MeV cannot cross the coulomb barrier of a Au nucleus, the (d,p) nuclear reaction can only take place with light nuclei. Therefore, the detected proton spectra contain only information on Si. A 20 µm thick absorber of pure gold is inserted between the sample to be studied and the detector in order to stop the incident deuteron beam completely even when the beam would cross a hole in the gold–silicon sample. The choice of a material containing only a heavy element (Au) as the absorber prevents any production of additional protons in this gold absorber during the deuteron irradiation.

The quantitative determination of silicon at different depths below the surface is based on the comparison of proton spectra obtained when ultrapure silicon and gold–silicon samples in the same geometrical

![Figure 13](image-url)
arrangement are bombarded. The silicon reference material is a thin foil (75 µm thick) of Si used in semiconductor technology. The corresponding depths in pure silicon and in gold–silicon alloys are calculated using the relative stopping power of pure silicon and that of the eutectic gold–silicon alloy (Figure 14). To scan the sample, a proton microbeam (5 µm × 5 µm) is rastered on the surface along 50 µm × 50 µm regions, a surface involving more than the area of one single flattened grain.

If the deuteron beam hits a gold grain boundary in which the diffusion of the eutectic alloy took place, a proton spectrum like that of Figure 14(a) may be observed showing a more important contribution in the medium and the low energy parts of the p₀ broad “peak” than when this deuteron beam hits a uniform silicon sample (Figure 14b). The depth distribution of Si in this particular case indicates that the relative concentration of Si is increasing from the surface to a region buried at several microns below the surface.

The map of Figure 15 corresponds to the silicon distribution at various depths below the surface irradiated at the rear part of the prepared gold foil. Figure 15(a) reflects the Si concentration at the bottom of the prepared foil which is reached by the most energetic protons. The regions of the proton spectrum shown in Figure 14(a) show schematically the corresponding regions in the depth of the 12-µm thick irradiated specimens. The incident beam was directed onto the face of the gold foil opposite to the face on which the Si deposition was made. In any region the silicon concentration does not exceed a few percent, a concentration well below that of the eutectic composition. This eutectic concentration is observed in Figure 15(i) which corresponds to grain boundary regions at the point where deuterons exit and at the surface where the silicon was deposited.

Nevertheless, in regions where silicon is detected only a liquid phase with a composition close to that of the eutectic could be admitted. The diffusion takes place so rapidly (a few minutes) that no appreciable solid state diffusion could be expected. Each concentration of silicon lower than 19% (as observed in nearly all parts of each map) can be understood by considering that the size of a grain boundary is narrower than the area of the incident deuteron beam. Scans like those of Figure 15 may then be converted into measurements of the width of the grain boundary filled with the eutectic alloy, the ratio of the measured silicon concentration on the eutectic composition being the ratio of the width of the grain boundary to the beam diameter.

5.5 Determination of Traces of Sulfur in Ancient Gold Artefacts

Investigations of the composition of archaeological artefacts made from precious metals require the use of nondestructive analytical techniques. PIXE and PIGE have been successfully applied in our laboratory for topographical elemental analysis of Fe, Cu, Zn, Ag, Cd, Sn and Au in uncorroded surfaces of jewellery items. The composition of the material in narrow regions of tiny solders on antique gold artefacts may give valuable information about the workmanship of ancient goldsmiths. In various papers, the hypothesis that in ancient times cadmium sulfide (a yellow mineral with a color close to that of gold) may have been “alloyed” with gold to obtain a material suitable for brazing has
been discussed. To test this hypothesis an experimental procedure for analyzing traces of sulfur in gold artefacts was developed. It is indeed expected that during the antique alloying procedure, traces of sulfur from cadmium sulfide were introduced in the brazing alloy.

Detection of energetic protons induced by deuteron bombardment of the specimen under investigation was achieved. The detector was situated at an angle of 135° with respect to the incident deuteron beam in order to facilitate the study of thick specimens often with an irregular shape. Sheets of mylar of uniform thickness (2.9 mg cm⁻² each) were inserted between the target and the detector in order to stop the scattered deuterons completely. Owing to the fact that most of the (d,p) reactions have a large positive $Q$ value, the proton energies are not significantly reduced by these absorbers.

Figure 15 Set of nine maps corresponding to the nine slices of Figure 14. Symbols (a) to (i) refer to the nine layers in the 12 µm thick sample. (Reprinted from S. Mathot, G. Demortier, ‘Three-dimensional Nuclear Microanalysis in Materials Science’, Nucl. Instrum. Methods Phys. Res., Sect. B, 77, 312–319. Copyright (1993) with permission from Elsevier Science.)
The best experimental condition for sulfur determination is obtained at \( E_d = 1.9 \text{ MeV} \), in which case the cross-section is sufficient and the \( p_0 \) and \( p_1 \) peaks are well resolved.\(^{57}\) Since the cross-section for 1.7 MeV deuterons is greater than at 1.9 MeV, working conditions at 1.9 MeV (on a thick sample) allow us to check for the presence of sulfur in the bulk and not only at the surface. Possible interfering elements (with their appropriate \( Q \) values) are within the scope of (d,p) reactions on S: Si, Mg, Cl, Ca (for \( p_0 \)) and Al, P, Cl, K, Mg (for \( p_1 \)).

The choice of detection angle and incident deuteron energy was then a determining factor in eliminating the

Figure 16 Experimental results from a (d,p) reaction induced on gold alloys prepared by an antique procedure (a) and in a soldering region of an antique jewellery artefact of the 9th century A.D. (b) Several peaks indicate the presence of Si and S. (Reprinted from G. Demortier, A. Gilson, ‘Determination of Traces of Light Elements in Gold Artifacts Using Nuclear Reactions’, Nucl. Instrum. Methods Phys. Res., Sect. B, 18, 286–290. Copyright (1987) with permission from Elsevier Science.\(^{57}\)
possible interferences. Detection of $p_0$ and $p_1$ protons provided a check for an interference-free investigation. This is because of the presence of both $p_0$ and $p_1$ signals for S outside the regions for Al($p_0 + p_1$) and (Si $p_0$) and the relative intensities of these peaks in comparison with a reference sample.

Sulfur and silicon (which were always introduced in metals when heating ores in antique metallurgy) are of crucial importance in understanding ancient technologies. Sulfur (in blende and greenockite) and silicon (in many minerals) may be expected to be present in narrow parts of the solder formed during the antique brazing of gold. Figure 16(a) shows the analysis of a soldering alloy that we prepared using this antique procedure: gold–cadmium alloys (with low melting point) are obtained by direct dissolution of CdS in a previously melted drop of gold. The concentrations of S and Si detected are, respectively, $120 \pm 35$ ppm and $50 \pm 15$ ppm. Note also the presence of C (from $^{13}$C) as an extra signal arising from the experimental set-up, i.e. a carbon (from oil in the pumping system) deposit on the target during the deuteron irradiation. The mylar absorber must have a thickness of $25 \text{mg cm}^{-2}$ in order to eliminate also protons from

* This low oxygen concentration, determined by neutron activation analysis, is not reliable with the expected value for a biological sample.
NUCLEAR REACTION ANALYSIS

(d,p) reactions on $^{12}\text{C}$. The concentration of Cd could be determined simultaneously by detection of characteristic X-rays induced by the same deuteron beam. The presence of residual sulfur (only at trace level) indicates that at least 95% of S was lost during the alloying procedure.

Figure 16(b) was obtained during the irradiation of a region of a soldered gold granule on a hollow gold pearl found in Syria (Hauran) with other more prestigious objects of Byzantine jewellery (9th century A.D.) (Figure 17).

The information from S (at concentration 30 ± 7 ppm) cannot be easily isolated from the large contribution of Si at the surface. The width of the peaks of Si present in this ancient artefact is much narrower than those observed in pure Si and in the soldering alloys formed by the methods available in antiquity (Figure 16a). The presence of traces of Si and often also traces of Al, can be attributed to dust inclusions in narrow regions of “porous” solders.

5.6 Particle-induced X-ray Emission, Particle-induced $\gamma$-ray Emission and Nuclear Reaction Analysis for Elemental Analysis of a Biological Reference Material

Bowen’s kale,\(^{(58)}\) a powder obtained by dry freezing this vegetable, was widely distributed in various laboratories to be certified for a reference material. Using various IBA techniques, it was possible to determine most of the main elements and traces quantitatively. Table 5 summarizes these results.\(^{(59)}\)

NRA induced by protons and deuterons was used for the determination of B, C, N, F and Na. The choice of a specific incident energy and the selected identification signal were determined for interference-free determination.

Compositions of various elements (from P or Ca) were obtained at low energy PIXE in order to minimize the X-ray absorption into the target itself. Traces of higher $Z$ elements were found using PIXE at 1.7 MeV in order to improve the sensitivity. Determination of hydrogen was not possible due to the rapid destruction of the sample powder during heavy ion irradiation (for ERD or NRA using $^{15}\text{N}$). The concentration of oxygen was established at 43%, a more reliable value than the previous determination using neutron activation analysis. The total content of this reference material using PIXE, PIGE and NRA exclusively (hydrogen not included) is 98.9 ± 3.5%.

1 INTRODUCTION

PIGE or prompt radiation analysis (PRA) is an analytical technique making use of γ-rays that are emitted during or immediately after bombardment of a sample with an ion beam. Here, discussion is restricted to prompt γ-ray emission. These are γ-rays that are detected during irradiation, in contrast to activation techniques where radiation is detected after irradiation. The technique has been used since the 1960s for analytical purposes. Sippel and Glover showed that PIGE with protons could be used for the determination of Mg and F in geological samples. Pierce et al. showed that deuterons could be used to determine C and Pierce et al. used 4 MeV protons to determine the amount of Si in several kinds of steel. At that time, the detection of γ-rays was mostly performed with NaI(Tl) detectors which have a relatively poor energy resolution, thereby limiting the analytical technique to the determination of one or two elements simultaneously. The development of Ge(Li) detectors with a much better energy resolution around 1970 made it possible to determine a number of elements in the sample simultaneously. Since then, studies have been carried out with light as well as heavy projectiles that showed that PIGE with a Ge(Li) detector is a powerful and sensitive method of multielemental analysis. In general, protons and α-particles are used as projectiles, but measurements have also been done with d, t, ³He, Li, B, N, F and Cl projectiles.

Besides the determination of concentrations in (thick) samples, PIGE can also be used to determine depth profiles by using narrow resonances in a cross-section of nuclear reactions. In general, PIGE is a technique that is less often used than other ion-beam analysis techniques like particle-induced X-ray emission (PIXE) or Rutherford backscattering spectroscopy (RBS). In PIXE or RBS spectra, elements appear in a relatively simple and systematic way, making interpretation and analysis of the spectra straightforward. In PIGE, the situation is more complex since even different isotopes of the same element result in completely different γ-spectra. Knowledge about the energy of resonances, the energy of the γ-rays, and interfering reactions in the sample must be available for each nuclide of interest. Interpretation and analysis of PIGE spectra can thus be much more complex than for PIXE or RBS spectra. This means that PIXE and RBS can be seen as general techniques to determine the composition of an unknown sample, while PIGE is used when the composition of the sample is more or less known and a γ-spectrum can be used to quantify the concentration or determine a concentration profile. PIXE (see PIXE (Particle-induced X-ray Emission)) is a technique that is generally used to determine elements
with \( Z > 12 \). PIGE is often used as a complementary technique to PIXE to determine light elements.

Although PIGE is regarded as a less general and versatile technique compared to PIXE, PIGE can have strong advantages. This is particularly the case for light elements \((Z < 11)\) that cannot be analyzed or are hard to analyze with PIXE. Moreover, PIGE produces totally different spectra for elements of neighboring \( Z \), removing peak-overlap problems between neighboring elements in the spectra. PIGE is only sensitive to specific isotopes, limiting the general applicability. It is, however, a powerful tool when isotopic analysis is required. Also, compared to similar PIXE spectra, minimal pile-up problems are present in PIGE spectra when there is no significant background radiation. Although PIGE is typically less sensitive than PIXE, the peaks in a PIGE spectrum are well separated and there is no need for absorption corrections for the \( \gamma \)-rays leaving the sample. This simplifies the experimental arrangement and the analysis of the spectra and can make the technique more attractive.

2 BASIC NUCLEAR PHYSICS

2.1 Principles of Nuclear Reactions

PIGE is based on nuclear reactions induced by accelerated beams that hit the sample of interest. After the reaction, nuclei in the sample remain in the excited states and decay by emitting \( \gamma \)-rays. The energies of these \( \gamma \)-rays are characteristic of the elements (isotopes). The two measured quantities thus yield the elemental identification and concentration, respectively. The technique is thus quantitative, or semi-quantitative when standards are used.

For a nuclear reaction to occur between a beam particle and a sample nucleus it is necessary that the beam energy exceeds the Coulomb barrier. The barrier energy (in MeV) can be estimated from Equations (1) and (2):

\[
E_c = 1.44 \frac{Z_1 Z_2}{d}
\]

with
\[
d = 1.25 \frac{A_1^{1/3} + A_2^{1/3}}
\]

where \( Z_1 \) and \( Z_2 \) are the proton numbers of the beam particles and the sample nucleus, respectively. The quantity \( d \) in fm \((1 \text{ fm} = 10^{-13} \text{ m})\) is approximately the sum of the two respective radii, with \( A_1 \) and \( A_2 \) the respective mass numbers. The approximation is based on the notion that nuclear forces have very short ranges \((\sim 1 \text{ fm})\). Thus the two colliding nuclei must almost touch each other. If the beam energy is smaller than \( E_c \), then the beam particle will be deflected by the nucleus. \( \gamma \)-Rays can still be produced in this case by Coulomb excitation of the nucleus. This, however, is not very likely for light ion beams and will not be discussed further because light-ion induced reactions will be treated as applying most frequently. These reactions encompass inelastic scattering, capture (or compound nuclear) reactions and particle transfer. For protons they are denoted as: \((p,p')\), \((p,\gamma)\) and, for instance, \((p,\alpha\gamma)\), respectively.

At low energy, \(< E_c \), only atomic excitations occur, giving rise to the emission of \( X \)-rays. This process is exploited in the PIXE method, as discussed in PIXE (Particle-induced X-ray Emission).

Equation (1) results in \( E_c = 1.2 \text{ MeV} \) for protons on \(^7\text{Li}, 4 \text{ MeV} \) on \(^{28}\text{Si}\), \(5.2 \text{ MeV} \) on \(^{40}\text{Ca}\) and \(13.6 \text{ MeV} \) on \(^{208}\text{Pb}\). For \( \alpha \)-particles on \(^{28}\text{Si}\), a beam energy of at least \( 7 \text{ MeV} \) is required. It is concluded that a proton beam energy of at least \( 1 \text{ MeV} \) is required and single-ended Van de Graaff accelerators, tandem Van de Graaff accelerators and cyclotrons are used for PIGE experiments.

The most commonly applied nuclear process in PIGE is the compound nuclear reaction, schematically written as Equation (3)

\[
a + A \longrightarrow C^* \longrightarrow B + b,
\]

with a representing the beam particle, A the target nucleus, \( C^* \) the compound nucleus (CN) in excited state that may decay by \( \gamma \)-rays or form a final product nucleus B and particle b. The product nucleus B, when formed in an excited state, \( B^* \), decays by \( \gamma \)-rays. The latter \( \gamma \)-rays are called reaction \( \gamma \)-rays, while those of \( C^* \) are \( \gamma \)-rays of the CN. Those \( \gamma \)-rays are characteristic of the sample nucleus A (see Figure 1), in particular from the well-known discrete low-lying states.

The CN model is based on the assumption that the probability of decay into any specific set of final products is independent of the means of formation of the CN. The decay of the CN level only depends on its energy. If the excitation energy is above the particle binding energy then it surely will decay via the particle channel, because particle decay, owing to its strong interaction, is much more likely than \( \gamma \)-ray decay with its electromagnetic interaction.

The excitation energy, \( E_x \), of the CN \( C^* \) can be calculated from Equations (4) and (5):

\[
E_x = Q + \frac{E_p m_A}{m_A + m_a}
\]

with
\[
Q = [m_C - (m_A + m_a)] c^2
\]

with \( Q \) the reaction \( Q \) value in MeV, when the masses are expressed in atomic mass units, \( u \), and the speed of light squared as \( c^2 = 931.5 \text{ MeV u}^{-1} \). In exothermic reactions mass is converted into energy and \( Q \) is positive, while
in endothermic reactions $Q$ is negative. In Equation (4) the laboratory beam energy $E_p$ is corrected by the mass factor of the two initial particles to obtain the energy in the center-of-mass system as an internal energy. The external energy or kinetic energy, $E_{\text{kin}}$, of the center-of-mass itself is written as Equation (6)

$$E_{\text{kin}} = \frac{E_p m_a}{m_A + m_a}$$

This energy is completely transferred to the recoiling CN as kinetic energy. The recoil energy may be of importance if the nuclear states involved in the decay of the CN have lifetimes shorter than the slowing down time of the recoil in the sample. In that case the $\gamma$-rays are emitted in flight and may show a shift and broadening in energy (see section 2.2).

Another important factor in PIGE analysis is the yield of $\gamma$-rays, which is directly connected to the reaction and emission probabilities. Here the reaction probability will be treated, while $\gamma$-ray emission is discussed in section 2.2.

The reaction probability is commonly expressed by the reaction cross-section $\sigma$, which represents a fictive surface at the nucleus through which the initial particle has to penetrate to induce a particular reaction. In many cases the cross-section exhibits a resonance-like behavior as a function of beam energy (Breit–Wigner shape), such as in proton capture or $(p,\gamma)$ reactions at relatively low energy. The width $\Gamma$ (in eV) of the resonance is a measure of the probability of forming that particular CN level and of decaying via $\gamma$-ray emission. The width $\Gamma$ is related to the lifetime, $\tau$, of the CN level via Equation (7), the uncertainty relation of Heisenberg:

$$\Gamma \tau = \frac{\hbar}{2\pi}$$

To distinguish the formation of the CN level from the decay probability, $\Gamma_p$ is introduced as the formation width (or probability) and $\Gamma_\gamma$ as the decay width. The reaction cross-section can then be expressed as a function of beam energy in Equation (8)

$$\sigma_{p,\gamma}(E) = \pi \hbar^2 g \frac{\Gamma_p \Gamma_\gamma}{(E - E_R) + \Gamma^2/4}$$

Here $E_R$ is the resonance energy at the maximum of the cross-section, $\hbar$ is the reduced wavelength of the initial particle and $g$ is a statistical factor, determined by the spins, $I$, $j$ and $J$ of the nuclear particles $A$, $a$, and $C^*$, respectively, Equation (9):

$$g = \frac{2J + 1}{(2J + 1)(2I + 1)}$$

For details see Deconninck. If the resolution of the beam is larger than the total width $\Gamma$, the total area $I_m$ under the resonance is obtained by integrating the cross-section over a broad energy range around the resonance, Equation (10):

$$I_m = 2\pi \hbar^2 g \frac{\Gamma_p \Gamma_\gamma}{\Gamma}$$

A Breit–Wigner resonance and its integral are shown in Figure 2.
In the case where $\Gamma$ is small (keV) the factor $(2J + 1)\Gamma_p \Gamma_\gamma / \Gamma$ is proportional to the integrated cross-section. Thus the factor is proportional to the sensitivity of the resonance reaction. The total width $\Gamma$ is contained in several nuclear data tables for many resonance levels in nuclei.\(^1\) From this it can be concluded that the value of the cross-section is not only important for sensitivity, but also for knowledge of resonance structures (Equation (8)) and, for practical applications, for the beam energy spread.

There are many other possible nuclear reactions yielding $\gamma$-rays that are resonant or nonresonant. Examples often used for elemental analysis are the inelastic scattering $(p, p' \gamma)$, and further $(p, \alpha \gamma)$ and $(p, n \gamma)$ with protons. With other beam particles, commonly used reactions are $(d, p \gamma)$, $(d, n \gamma)$ and $(\alpha, n \gamma)$. At relatively low beam energies, in the few megaelectron volts region, the $(p, p' \gamma)$ and the $(p, \alpha \gamma)$ reactions also show resonant structures. Therefore Equation (8) can be used to find the cross-section by replacing $\Gamma_\gamma$ for the exit channel by $\Gamma_p$ and $\Gamma_\alpha$, respectively. In the cases where the cross-section does not show resonant behavior, but varies only slowly with beam energy, the cross-section can be taken to be constant or averaged over the relevant energy region.

For nonresonant reactions, Equation (11) can be used to calculate the $\gamma$-ray yield $Y(E_0)$ at an incident energy $E_0$ of particle $x$ on a target containing element $A$ with atomic mass $A_x$ (in g mol\(^{-1}\)), concentration $c_A$ and with a cross-section $\sigma_{x, \gamma}(E)$, according to Equation (8), to produce particular $\gamma$-rays:

$$Y(E_0) = N_p c_A A_x^{-1} N_{av} e(E_\gamma) \frac{\Omega}{4\pi} \frac{E_i}{E_0} \frac{\sigma_{x, \gamma}(E)}{\epsilon(E)} \text{d}E$$

where $N_p$ is the number of particles $x$ hitting the target, which can be deduced from the measured beam current and time. $N_{av}$ is the Avogadro number, $e(E_\gamma)$ is the efficiency of the detector for the particular $\gamma$-ray and $\Omega$ is the solid angle of the detector (in steradians). The cross-section $\sigma_{x, \gamma}(E)$ (cm\(^2\), note 1 barn = 10\(^{-24}\) cm\(^2\)) and the stopping cross-section $\epsilon(E)$ (MeV g\(^{-1}\) cm\(^2\)) are integrated over the energy from $E_0$ to $E_i$, the energy of the particle $x$ when leaving the target at the back side. Equation (11) also represents the thick-target yield, by putting $E_i = 0$, corresponding to the incident particle coming to a complete stop in the sample. The thick-target yield in literature is often expressed in units of (μC sr\(^{-1}\)), that is in counts per quantity of electric charge on the target and per unit of solid angle. This can be derived easily from Equation (11) by dividing out $N_p$ (expressed as charge) and $\Omega$. The cross-sections and the stopping cross-sections of particle $x$ slowed down in the sample have been tabulated in various publications for many particles, energies and stopping materials (see e.g. Nuclear Data Tables\(^{12}\) for reaction cross-sections and Ziegler et al.\(^{13}\) for stopping powers). If they are not tabulated then the known values must be interpolated or, in the worse case, measured. In Equation (11) the attenuation of $\gamma$-rays in the target, in possible absorbers and in the detector window is neglected, but it must be taken into account when $\gamma$-ray energies are low.

For detailed formulas in cases of sharp and broad resonances the reader is referred to Deconninck.\(^1\) To circumvent the problems involved in the use of absolute cross-sections and stopping powers, internal or external standards are often used to compare with the measurement on the real sample. In the case where internal standard elements are added, their concentrations and cross-sections must be known precisely. In the case of an external standard, a sample is prepared with exactly the same elements as the sample of interest, at known concentrations. In the first case only one measurement is needed, but integrations for the different elements (Equation (11)) are still necessary. However, beam current and detector solid angle are canceled. In the second case the integrations are canceled, but beam current (and solid angle, if different) need to be measured.

For thin samples the cross-section can be considered constant. It is convenient to add a standard element with mass number $A_x$ and with known concentration $c_s$ to the sample. When comparing the $\gamma$-ray yields of element $A$ and standard $S$, not only are the solid angles and number of beam particles canceled, but so too are the stopping powers because in both cases they are the same. The
unknown concentration $c_A$ can easily be calculated from the measured $\gamma$-ray yields from Equation (12):

$$c_A = \frac{Y_A \sigma_{\gamma A} A_A}{\sum Y_i \sigma_{\gamma i} A_i}$$  \hspace{1cm} (12)

### 2.2 $\gamma$-Ray Emission

$\gamma$-Ray emission is governed by the electromagnetic interaction and transitions are described by connecting the initial and final nuclear quantum states via the electromagnetic multipole operator. The electromagnetic field can be expanded in terms of multipoles, i.e. monopole, dipole, quadrupole, octupole, and so on. They can be of electric or magnetic character, with certain constraints. The multipole moments have the form of Equation (13):

$$M_l \propto r^l Y_l^m(\theta, \phi)$$  \hspace{1cm} (13)

where $l$ represents the order of the multipole moment and $Y_l^m(\theta, \phi)$ is the spherical harmonic function. The electromagnetic operator, which acts on the initial and final states involved and gives rise to the $\gamma$-ray transition, also has the basic form of Equation (13). For a detailed treatment of the electromagnetic features important for $\gamma$-ray emission the reader is referred to text books, for example by Krane\(^{(14)}\) and Ejiri and de Voigt\(^{(15)}\). Here we will restrict ourselves to the more practical rules that determine the nature and intensity of $\gamma$-rays.

The electromagnetic transition probability $T(E(M), l)$, according to Equation (7), is given by Equation (14):

$$T(E(M), l, i) = \frac{\Gamma(E, (M), l, i)}{\hbar} = \frac{\Gamma_y}{\hbar} = \frac{1}{\tau}$$  \hspace{1cm} (14)

The radiation width $\Gamma_y$ of Equation (7) is thus equivalent to the transition probability $T$, which depends on the electric ($E$) or magnetic ($M$) character, on the multipolarity $l$ of the radiation and on the structure of the initial and final nuclear states ($i$). The multipolarity $l$ of the transition corresponds to the order $l$ of the multipole moment and of the multipole operator (Equation 13). The transition probability depends on external factors, i.e. the energy $E_y$ of the transition, the multipolarity $l$ and the nuclear radius $R$, as well as on the internal factors (i.e. the nuclear structure of the initial and final states). The latter information is not always available and varies strongly from nucleus to nucleus and even within a nucleus from state to state. Therefore we will discuss the general consequences of the external factors and refer the reader to the various nuclear data compilations for the internal factors; i.e. for nuclei with mass 21–44 to the compilation of Endt\(^{(10)}\) (and references quoted therein) and for nuclei below mass 21 to the compilation of Ajzenberg–Selove\(^{(11)}\) (and references quoted therein).

The importance of the external and internal factors is that they also determine the value of $\Gamma_y$ and thereby the cross-section $\sigma_{\gamma A}$, according to Equation (8) and thus the yield $Y(E_0)$, according to Equation (11). A simplified indication for the external factor $T_{ex}$ can be obtained from Equations (15) and (16):

$$T_{ex}(E) \propto \frac{E_y^{2l+1}}{\hbar c} R^{2l}$$  \hspace{1cm} (15)

and

$$T_{ex}(M) \propto \frac{E_y^{2l+1}}{\hbar c} R^{2l-2}$$  \hspace{1cm} (16)

Noting that $\hbar c = 197$ MeV fm, that $E_y$ is of the order of 1 MeV and that the nuclear radius is about 3 fm for light nuclei, one concludes that the transition probability decreases rather strongly with increasing multipolarity of the radiation. For each unit of $l$ the difference is about a factor of $10^4$. The electric transitions are more probable than the magnetic ones of the same multipolarity by a factor of $R^2$, which is about a factor of 10 for light nuclei. Note that these are only rough estimates and that the internal factor may change the picture quite drastically. For instance in collectively rotating nuclei, in the strongly deformed regions, the electric quadrupole ($E_2$) transition is strongly enhanced. Nevertheless, it is probably safe to state that in general the sequence of probability for transitions to occur is $E_1$, $M_1$, $E_2$, $M_2$, $E_3$, $M_3$, $E_4$, $M_4$, and so on. The transition probability increases strongly with the transition energy, particularly for the higher multipoarities. This is illustrated in Figure 3, where absolute transition probabilities are given for one-particle transitions, i.e. transitions caused by one (valence) proton in the nucleus.

The energy of the $\gamma$-ray is simply the energy difference between the initial and final states, Equation (17):

$$E_y = E_i - E_f$$  \hspace{1cm} (17)

here $E_i$ and $E_f$ represent the excitation energies of the initial and the final states, respectively. In this formula the recoil energy of the de-exciting nucleus is neglected. It can be calculated from the $\gamma$-ray energy and mass, $M$, of the nucleus as Equation (18):

$$E_{rec} = \frac{E_y^2}{2Mc^2}$$  \hspace{1cm} (18)

Noting that the numerator is of the order of megaelectron volts and the denominator of gigaelectron volts, $E_{rec}$ is only about $10^{-2}E_y$, thus mostly of the order of kiloelectron volts, which can be neglected.

The multipolarity of the $\gamma$-radiation is restricted by the spins (and parities) of the initial and final states $I_i, (\pi_i)$...
and $I_i (\pi_i)$, respectively. The multipole radiation of order $l$ (Equation 13) carries $l$ units ($\hbar$) of angular momentum per photon. Conservation of angular momentum and the notion that its couplings are vectorwise leads to the rule, Equation (19):

$$|I_i - I_f| \leq I_i + I_f$$

(19)

It thus appears that for certain spin combinations more than one multipolarity is allowed. In that case the lowest allowed multipolarity is the most probable one with mixing of the next higher one, for which $l$ is one unit larger. The parities of the initial and final states, $\pi_i$ and $\pi_f$, are also important for the electric or magnetic character. Conservation of parity, with $\pi_f$ the parity of the emitted $\gamma$-ray with multipolarity (angular momentum) $l$, leads to the rule, Equation (20):

$$\pi_f = \pi_i \pi_l$$

(20)

The parity $\pi_f$ of electric transitions is determined by Equation (21):

$$\pi_f(E) = (-1)^l$$

(21)

The parity $\pi_f$ of magnetic transitions is determined by Equation (22):

$$\pi_f(M) = (-1)^{l+1}$$

(22)

The consequences of the latter two rules are that electric transitions with even multipolarity $l$ and magnetic transitions with odd $l$ have even parity; thus $M_1, E_2, M_3, E_4, M_5, E_6$, and so on have even parity. Consequently $E_1, M_2, E_3, M_4, E_5, M_6$, and so on have odd parity. With the rules shown in Equations (19)–(22) and from the known spins and parities of the initial and final states the character of the radiation can be determined and thereby the probability of the radiation and its intensity as far as these factors are concerned. The following examples will illustrate the simplicity of the rules:

**Transition 1**

$1^+ \rightarrow 0^+$ $M_1$ radiation only possible

$1^- \rightarrow 0^+ E_1$

$2^+ \rightarrow 0^+ E_2$

$3^+ \rightarrow 2^+ M_1, E_2, \ldots, M_5$. In practice only $M_1, E_2$ mixed.

$1^- \rightarrow 2^+ E_1, M_2, E_3$. In practice only $E_1, M_2$ mixed.

Note that the transition $0^+ \rightarrow 0^+$ cannot proceed via $\gamma$-radiation because the intrinsic spin of a photon is $1^-$. In this particular case the transition is fully converted to conversion electrons. All other transitions are also for a minor fraction converted, but the conversion coefficients are rather small, particularly for low multipolarity radiation and high transition energies. For instance, at $300$ keV for $E_1$ radiation the conversion is already below $1\%$, but for $M_4$ radiation, electrons and $\gamma$-rays have about the same probability. For further detail see, for example, Krane{superscript(14)} and Ejiri and de Voigt{superscript(15)}.

It should be realized that $\gamma$-rays generally are not emitted isotropically in space. Asymmetry can be as much as $50\%$. The shape of the angular distribution depends on the angular momentum transfer in the reaction and on the population of the initial state and the final nucleus, as well as on the character (multipolarity) of the radiation. Quadrupole radiation, for instance, has its maximum along the direction of the beam, while dipole radiation peaks in directions perpendicular to the beam direction. For absolute values, measured angular distributions must be used or can be calculated on the basis of known

---

**Figure 3** One-particle transition probabilities as functions of the $\gamma$-ray energies for various multipole radiations.
or assumed angular momentum alignments (see e.g. Krane\(^{(14)}\)).

Finally, the energy shift and broadening of the \(\gamma\)-ray lines in the spectrum, which are due to the Doppler effect, should be mentioned. When a \(\gamma\)-ray is emitted during the flight of the excited nucleus through the sample or in vacuum behind the sample, the energy measured will be Doppler shifted. This is the case when the lifetime of the nuclear excited state is smaller than the average slowing down time of the recoiling nucleus in the sample. This time depends on the initial velocity of the recoil and on the slowing down material, but generally has values in the range of \(10^{-8} - 10^{-14}\) s. The measured \(\gamma\)-ray energy is then given by Equation (23):

\[
E_\gamma = E_{\gamma 0} 1 + \frac{v}{c} \cos \theta
\]

(23)

where \(E_{\gamma 0}\) is the unshifted energy, \(\theta\) the angle of observation with respect to the beam direction and \(v\) is the velocity of the recoiling nucleus. In the case of compound nuclear reactions the initial velocity can be calculated easily from Equation (6) as Equation (24):

\[
\frac{v}{c} = 0.04635 \sqrt{m_n E_p} \frac{m_A + m_a}{m_A}
\]

(24)

The masses are given in mass numbers and the energy in MeV, resulting in the ratio \(v/c\). Almost all nuclear lifetimes of compound states, mostly highly excited states, are very short, of the order of \(10^{-14} - 10^{-15}\) s. The corresponding de-exciting \(\gamma\)-rays are thus fully Doppler shifted and broadened, depending on the angle of emission and on the detector solid angle. Low-lying excited states may have much longer lifetimes and the corresponding \(\gamma\)-rays will not be affected by the Doppler effect. The resulting sharp lines are generally more useful for elemental analysis.

\[\text{PARTICLE-INDUCED } \gamma\text{-RAY EMISSION} \]

2.3 Principles of Depth Profiling

Charged-particle induced resonance reactions offer the possibility of obtaining the depth in the sample from which the \(\gamma\)-radiation is emitted and thus determining the depth profile of the elements. The leading principle is based on the fact that the beam particles are slowed down in the sample and thus the beam energy has to be increased to match the value of the resonance. The amount of increase \(\Delta E\) (keV) depends on the depth \(\Delta x\) (cm) and the two quantities are related via the stopping power \(S\) (keV cm\(^{-1}\)) by Equation (25):

\[
\Delta x = \frac{\Delta E}{S}
\]

(25)

In compilations (see e.g. Ziegler et al\(^{(13)}\)) the stopping cross-section \(\varepsilon\) is often given in units of keV atom\(^{-1}\) cm\(^2\).

Here \(\varepsilon\) is defined by Equation (26) as:

\[
\varepsilon = \frac{\Delta E}{N \Delta x}
\]

(26)

where \(N\) is the atomic density in the sample (at cm\(^{-3}\)). It should be noted that the depth resolution depends on the straggling in the sample, on the resonance width and on the spread in beam energy. It is therefore important to select resonances that are as narrow as the beam spread (keV).

Thus, the depth \(\Delta x\) can be calculated from the difference between the resonance and the beam energy, the stopping cross-section and the atomic density. The atomic density can be expressed in terms of the mass density \(\rho\) (g cm\(^{-3}\)) as Equation (27):

\[
N = \frac{\rho N_{av}}{M}
\]

(27)

where \(N_{av}\) is the Avogadro number \((6.022045 \times 10^{23}\text{ mol}^{-1})\) and \(M\) is the molecular or atomic weight.

The stopping cross-sections are tabulated (for example in Ziegler et al\(^{(13)}\)) for elements. In the case of a compound a simple rule called Braggs rule may be applied, Equation (28):

\[
\varepsilon = \sum_i c_i \varepsilon_i
\]

(28)

where \(c_i\) are the mass concentrations or the atomic fractions in a molecule.

3 PARTICLE-INDUCED \(\gamma\)-RAY EMISSION

3.1 Basic Principles of Particle-induced \(\gamma\)-Ray Emission

In PIGE, samples are bombarded with a beam consisting of light particles (protons, deuterons, tritons, \(^3\)He or \(^4\)He (\(\alpha\))) or heavy ions. The energy of the incident particles is usually in the range of 1–4 MeV amu\(^{-1}\). The beam enters a vacuum chamber, in which the sample is placed, through a set of diaphragms and the emitted \(\gamma\)-rays are detected by, for example, a hyperpure Ge or Ge(Li) detector. The pulses from the detector are analyzed by a multichannel analyzer (MCA). A more detailed description of the experimental set-up can be found in section 3.5. A typical PIGE energy spectrum is shown in Figure 4.

This type of energy spectrum consists of a number of peaks corresponding to the \(\gamma\)-rays related to the elements present in the sample. These characteristic peaks are superimposed on a background that originates from Compton scattering of \(\gamma\)-rays in the detector. The number of counts in a peak of a certain element corresponds
to the amount of that element in the sample under investigation. All the parameters that determine the number of counts in a certain peak are known or can be measured. Using computer programs and databases, an absolute determination of the amounts of the elements in the sample is possible.

A complication in the spectra can be that the same γ-rays could result from two different reactions. For example, consider the reactions \(^{26}\text{Mg}(p,\gamma)^{27}\text{Al}\) and the \(^{27}\text{Al}(p,p'\gamma)^{27}\text{Al}\) which both give γ-rays with an energy of 843 keV and 1023 keV. Magnesium should then be identified by the \(^{25}\text{Mg}(p,p'\gamma)^{25}\text{Mg}\) reaction which produces γ-rays of 586 keV. Aluminum can be identified by the \(^{27}\text{Al}(p,\gamma)^{28}\text{Si}\) reaction with γ-rays of 1778 and 2836 keV.

Prompt γ-rays can originate from different types of nuclear reactions such as \((p,p'\gamma)\), \((p,\alpha'\gamma)\), or \((p,\gamma)\) for protons, and \((d,n\gamma)\), \((\alpha,\alpha'\gamma)\) and so on for other projectiles. When an element consists of more than one isotope, γ-rays can be produced in any of the isotopes and this will show up in the accompanying spectra as more lines belonging to one element but different isotopes. This leads to isotopic determination.

### 3.2 Possible Reactions and Their γ-Ray Energies

In a PIGE spectrum, the peaks are characteristic of different elements or even different isotopes of elements present in the sample under investigation. In Table 1, the most intense proton reactions together with the energy of the emitted γ-rays are presented for elements with \(4 < Z < 20\). In Table 2, the most intense proton reactions for a number of heavy element isotopes are presented.

The elemental contents are obtained from isotopic contents, taking the natural abundances into account.

### 3.3 Sensitivity

A general discussion about the sensitivity of PIGE for different kinds of sample is difficult to give since it depends on the content of the major elements (the matrix), the minor elements and the trace elements in the sample. There are several ways to define the sensitivity of an analytical method.

The first and commonly used way to define sensitivity is by the minimal detectable concentration or limit of detection (LOD). It is defined by Equation (29)

\[
\text{LOD} = k\sigma_b,
\]

where \(\sigma_b\) is the standard deviation of the background under a (certain interval of a) peak of interest in a spectrum, and \(k\) is a factor reflecting the desired confidence level. It can be interpreted more easily with the help of Figure 5.

In this figure, the energy interval \(\Delta E\) is taken as the detector resolution and is equal to the full width at half-maximum (fwhm) of the peak. \(I_Z\) is the number of counts in the peak and \(I_b\) is the number of counts in the background under the peak. Both are the number of counts in the energy interval \(\Delta E\). The standard deviation \(\sigma_b\) is taken to be the standard deviation of the background counts \(I_b\). The confidence level \(k = 3\), gives a confidence level of 99.98% for normally distributed measurements. This means that a peak is considered to be detectable if, Equation (30):

\[
I_Z > 3\sqrt{I_b}
\]
Systematic studies concerning sensitivities have been performed by Deconninck and Demortier \cite{5,6} with protons, Clark et al. \cite{20} with protons and α-particles, Borderie et al. \cite{19,21} with tritons and α-particles, Giles and Peisach \cite{71} with α-particles and Borderie et al. \cite{23} with heavy ions. Of about 70 elements studied, 40 can be determined with high sensitivity (<100 ppm). Trace element sensitivity (ppm range) can be obtained for the light elements Li, Be, B, N, O, F, Na and P. \cite{23}

In Figure 6, it can be seen that protons and α-particles are the best choice for the determination of light elements. Heavy ions can be used for the determination of medium and heavy elements at a level around 50 ppm. Accurate determination of concentrations in samples depends on the LOD and on the presence of major and minor elements in the sample. As a rule of thumb, accurate determinations can be performed at concentration levels around 10 times the LOD.

The second way to define sensitivity is to express it as the minimum absolute amount that can be detected. The absolute amount can be calculated from the concentration of an element if the areal mass density (g/cm²) of the sample is known. The minimal amount of light elements is in the range 10⁻¹⁰⁻¹⁰⁻¹¹ g. The lower limit in the absolute amount is obtained with the ion microprobe technique (see section 3.5). Here, a beam diameter below 1 μm can

be used$^{[24]}$ making detection of an absolute amount of $10^{-15}$ to $10^{-12}$ g possible, although measurement times can be very high if concentration distributions have to be determined.

The third way is to use the thick-target yield (Equation 11) as a way to compare different elements, projectiles, energies and so on. The advantage of this method is that PIGE is most often used for the analysis of thick samples. A thick sample means a sample in which the incident particle is completely stopped. Generally, in thin samples the sensitivity is poor compared to thick samples. There is a strong energy dependence of the excitation curve, and the sample weight and composition should be known accurately.$^{[25]}$
Figure 5 Limit of detection.

Figure 6 LOD of a number of elements using PIGE for different projectiles (adapted from Borderie\textsuperscript{23} and references therein). ●, \textsuperscript{35}Cl at 55 MeV; ○, p; ●, t; △, α; light projectiles at \( E \leq 5 \text{ MeV} \).

Several authors have published tables with thick-target yields.\textsuperscript{(7,16–18,25,26)}

Kenny et al.\textsuperscript{25} measured the absolute thick-target yield for several elements at incident proton energies of 2.0 and 2.5 MeV. They measured the yields for several \( \gamma \)-ray lines for elements ranging from F to Au. In Figure 7 the thick-target yield is plotted as a function of the atomic number \( Z \) for the strongest \( \gamma \)-ray line of an element. It can be seen that the yield, and thus the sensitivity, is highest for the light elements.

Figure 7 Thick-target yields of the strongest \( \gamma \)-rays for a proton energy \( E_p \) of 2 MeV (●) and 2.5 MeV (○). (The figure is drawn with data taken from Kenny et al.\textsuperscript{25})

Figure 8 Cross-section for the production of 0.109, 0.197, 1.24 and 1.36 MeV \( \gamma \)-rays from the inelastic proton scattering reaction on fluorine (from Ranken et al.\textsuperscript{27}).
Other datasets are presented by Anttila et al.\(^{16}\) and Kiss et al.\(^{17}\). They present thick-target yields for several proton energies between 1.0 and 4.2 MeV for isotopes with \(4 < Z < 21\). Thick-target \(\gamma\)-ray yields for heavy elements (\(Z > 30\)) were determined by Räisänen and Hänninen\(^{18}\) for 1.7 and 2.4 MeV protons. Thick-target \(\gamma\)-ray yields for light elements with 2.4 MeV He\(^+\) are given by Lappalainen\(^{26}\) and prompt \(\gamma\)-rays generated by 5 MeV \(\alpha\)-particles were investigated by Giles and Peisach\(^{7}\) who determined the sensitivity of elements ranging from lithium to hafnium.

In the following, a few examples of excitation curves (cross-section versus particle energy) will be given. In Figure 8 the cross-section for the \(^{19}\)F(p,p\(^0\)\(\gamma\))\(^{19}\)F inelastic scattering reaction is given\(^{27}\) for four different \(\gamma\)-rays (109 keV, 197 keV, 1.24 MeV and 1.36 MeV).

For magnesium, excitation functions of \(^{24}\)Mg, \(^{25}\)Mg and \(^{20}\)Mg were determined by Boni et al.\(^{28}\). Taking into account the isotopic abundances, the 1369 keV \(\gamma\)-ray from \(^{24}\)Mg(p,p\(^0\)\(\gamma\))\(^{24}\)Mg has the highest cross-section. As an example, this excitation function is given in Figure 9 for beam energies from 2.8 to 3.8 MeV.

A proper excitation curve is measured such that angular distribution effects are averaged out. For this purpose a large solid-angle detector is often positioned at an angle of 55° with respect to the beam direction.

3.4 Background

The LOD of an element can be calculated with the help of Equation (30) and is determined by the background radiation under the peak. The background can be caused by minor or major elements in the sample under investigation but also by the experimental set-up and/or the detector.

The background caused by the minor and major elements is dependent on the type and energy of the projectiles. The background is mainly caused by Compton scattering in the detector, depending on the response function and on the \(\gamma\)-rays reaching the detector. These \(\gamma\)-rays can be generated by competing nuclear reactions in the sample and in the surrounding materials.

\(\gamma\)-Radiation can also be produced by reactions taking place in the diaphragms in front of the vacuum chamber, the (aluminum) beam pipe, the vacuum chamber itself, and the Faraday cup used to measure the beam current. In the design of the vacuum chamber care has to be taken to use materials that do not produce large numbers of \(\gamma\)-rays. Light ions, particularly those induced by deuterons, cause more severe background effects than heavy ions. This is mainly due to the lower Coulomb barrier and to the many reaction channels that are open. Precautions have to be taken so that materials do not contain contaminations that can produce \(\gamma\)-rays. Another problem could be natural radioactivity in the surroundings of the experimental set-up. Although the intensity generally is too low to be of any influence, in time-consuming experiments or in cases where a very low detection limit is required, this background can be of importance. To prevent any influence of the surroundings, lead shielding of the detector should be used. Aged lead exhibits less activity than new material.

3.5 Experimental Set-up and Procedures

In this section a typical experimental arrangement to perform PIGE experiments will be presented together with some experimental procedures.

3.5.1 Accelerator and Beam Guidance System

Most PIGE experiments on light elements are performed with energies between 1 and 4 MeV amu\(^{-1}\). This energy is also ideally suited to performing simultaneous measurements with PIXE and/or RBS. In this case a single-ended Van de Graaff accelerator or pelletron accelerator is well suited to perform the PIGE experiments. If reactions are to be used where higher energies and/or heavy ions such as \(^{15}\)N are necessary, tandem accelerators or cyclotrons should be used. In order for the accelerator to perform depth profiling, an easily changeable beam energy and

![Figure 9](image_url)
good energy resolution are required. This excludes a cyclotron for depth profiling, unless improvement of the beam quality is obtained, for example by means of a dispersive system.\textsuperscript{(24)}

Usually, the accelerator is connected to a so-called analyzing magnet which selects a beam with a desired energy for a specific ion. The calibration of the analyzing magnet is usually done by means of a suitable resonant nuclear reaction. Nonlinearity and hysteresis effects of the magnet can make the calibration procedure and the setting of the magnetic field to the correct value critical if great accuracy in the beam energy is required.

Sometimes a proton beam is used\textsuperscript{(20)} with an increased energy spread to make the excitation function more or less flat without any resonance structure. In this case it is not necessary to know the exact value of the beam energy from the accelerator.

The beam is transported to the irradiation chamber through evacuated pipes by means of bending magnets which bend the beam and electrostatic quadrupole lenses which focus the beam. The size of the beam on the target is usually in the range 0.5–5 mm in diameter but can be focused down to below 1 µm in a microprobe set-up.

### 3.5.2 Irradiation Chamber

Many possible layouts of the irradiation chamber are used to perform PIGE analyses. In Figure 10, a possible layout is presented where most of the commonly used features are included. The targets can be mounted on a one- or two-dimensional translation stage. This allows for multiple samples to be mounted and measured without breaking the vacuum by the application of micrometers or stepper motors. Moreover, the surface of the sample can be scanned if inhomogeneities in the sample are expected. One target position is mostly occupied with fluorescent quartz. It can be used to observe and align the beam spot on the target. For the majority of applications it is useful to be able to detect several types of radiation and particles from the sample. Besides a Ge(Li) detector to detect high energy γ-rays (PIGE), a Si(Li) detector to detect X-rays (PIXE) and a surface barrier detector to detect scattered particles (RBS) are usually mounted in the irradiation chamber.

For quantitative measurements, the beam charge can be determined in several ways. With thin samples in which the incident particles are not stopped, a Faraday cup behind the sample can be used to determine the beam charge accurately. With thick samples a rotating vane in front of the sample can be used or the beam charge can be determined from a beam current measurement from the sample itself. In all cases, care has to be taken to prevent secondary electrons from the target reaching the Faraday cup by applying secondary electron suppressor rings near the target and/or in front of the Faraday cup.

### 3.5.3 Detectors

The γ-rays in a PIGE experiment can be measured either by a scintillator (NaI(Tl)) or by bismuth–germanium–oxide (BGO), a Ge or a Ge(Li) detector. A detailed description of these detectors can be found in a textbook by Knoll.\textsuperscript{(30)} The NaI(Tl) detector has a relatively poor energy resolution (about 6% at 662 keV) combined with a high efficiency. It can be used in experiments where the energy resolution is not critical but efficiency is important, for example in depth profiling experiments where high efficiency is needed. BGO detectors have the advantage of a higher efficiency than NaI(Tl) for a given size crystal and a better peak-to-Compton ratio. The compact set-up makes BGO well suited to exploiting weak resonances. The superior energy resolution of a Ge detector (<2 keV at 1.33 MeV), a relatively high efficiency and a large peak-to-Compton ratio means that the Ge detector is mainly used in experiments to determine the bulk concentration of complex samples. The energy resolution is high enough to distinguish γ-rays from competing reactions and to analyze interfering peaks in the spectrum. For low-energy γ-rays, use of a planar hyperpure germanium detector can be very useful.\textsuperscript{(23)} It has an energy resolution of about 500 eV at 122 keV.

![Figure 10 Example layout of a vacuum chamber to perform PIGE experiments (from Borderie\textsuperscript{(23)} and references therein).](image-url)
3.5.4 Electronics

The detectors are connected to charge-sensitive preamplifiers and the resulting pulses are amplified in a spectroscopy amplifier. Shaping and filtering in these amplifiers are used to improve the signal-to-noise ratio. Next, the pulses are fed into a MCA. The analog-to-digital converter (ADC) part of the MCA usually has a resolution of 12 bit (4096 channels), although sometimes a higher resolution is used. The conversion time of the ADC has to be fast enough to prevent dead time problems, especially during high-count-rate experiments. Usually, a conversion time below 10 µs is applied.

3.5.5 Calibration and Spectrum Analysis

First, the γ-ray detection system has to be calibrated. This can be carried out quite easily by using a set radioactive source such as 60Co, 208Tl or 207Bi, depending on the energy region of interest. As an example, in Figure 11, a calibration spectrum is presented. Several peak-fitting routines exist to find the significant peaks and to determine accurately their (channel) positions in the spectrum. To analyze a spectrum, first the peaks have to be identified and possible overlap problems solved. The high energy resolution of a Ge(Li) detector and the limited number of γ-rays means that the peaks in a PIGE spectrum are usually well separated without overlap problems. The actual calibration is usually performed by fitting a linear (or higher) polynomial function between the energy of the peaks in the spectrum and their corresponding positions. The second step is to determine the intensities of the peaks. This is generally performed by a computer code. This computer code is usually also equipped with an automatic peak search algorithm making analysis of PIGE spectra easy to perform. Finally, the intensities of the peaks combined with a sensitivity calibration give the concentration of the isotopes present in the sample.

The precise beam energy has to be determined, particularly for depth profiling. This can be done by a number of reactions with narrow and strong resonances, depending on the energy of interest; e.g. the reaction 27Al(p,γ)28Si with a resonance energy of 991.90 ± 0.04 keV and 15N(p,α)12C with 429.57 ± 0.09 keV.

3.5.6 Target Preparation

Generally, the target preparation of PIGE samples is easy; just use them as they are. Some geological samples can be polished into sections, 20 µm thick, which allow investigation with an optical microscope. Powdered samples can be pressed into pellets and analyzed directly. Biological materials can be freeze-dried and measured. When liquids have to be analyzed, more complicated procedures have to be followed or an external beam has to be used (see below). In microbeam analysis, care has to be taken not to lose the integrity of the sample during preparation. In the analysis of light elements in biological samples this can be especially difficult to accomplish.

3.5.7 External Beam

Samples such as liquids, wet biological samples or objects with large dimensions cannot be placed inside an evacuated irradiation chamber. These samples can be analyzed with an external beam set-up where the beam exits the beam pipe through a thin foil which is often cooled. The sample is often placed in a helium atmosphere to decrease target heating and to increase the particle range of the protons (and thus diminish straggling) since stopping for hydrogen in helium is low.

3.5.8 Microbeam

A focused microbeam can be used to determine lateral distributions of elemental concentrations on a scale of about 1 µm. A microbeam set-up requires an object and aperture diaphragm combined with a number (2–4) of magnetic quadrupoles to focus the beam down to micrometer sizes. The focusing principles, problems, and applications can be found in a textbook by Watt and Grime.

3.6 Depth Profiling

Several isotopes have the potential for depth profiling, for instance 1H, 13C, 15N, 18O, 19F, 22Ne, 23Na, 24Mg.
PARTICLE-INDUCED $\gamma$-RAY EMISSION

$^{26}$Mg, $^{27}$Al, $^{29}$Si, $^{30}$Si. Most of these light nuclei have sharp and strong resonances in the excitation curve. The instrumentation for performing depth profiling is discussed in section 3.5. Additional requirements for the accelerator are a good energy resolution and the capability to change the energy easily. High-energy resolution of the beam is required in applications where narrow resonances are used. A detailed description of depth profiling can be found in Hirvonen.(31)

4 APPLICATION OF THE PARTICLE-INDUCED $\gamma$-RAY EMISSION TECHNIQUE

Possible applications range from geological and archeological samples, steel samples, dust and aerosol samples to biomedical samples. In this section only a few examples are presented of PIGE analyses to serve as illustrations.

Van IJzendoorn et al.(35) used the PIGE technique to quantify thin layers of SiF$_x$ that were a result of reactive ion etching of Si wafers with a CF$_4$ plasma. The quantification is important to understand the etching process. The $^{19}$F(p,p'\gamma)$^{19}$F reaction was used to determine F on the Si wafer. A proton energy of 2.78 MeV was chosen to suppress a Si reaction and thus limit the Compton background. An example of a $\gamma$-ray spectrum is given in Figure 12.

In Figure 13 an example of the analysis of a hafnium plate is presented.(18) The hafnium plate is bombarded with 10 mC of 2.4 MeV protons. In the spectrum the following elements can be seen: O (150 ppm), Na (0.3 ppm), Al (30 ppm) and P (5 ppm). Also heavier elements including Zr (2.8%), Fe (100 ppm) and Cu (<50 ppm) can be observed.

An example of depth profiling with the $^{15}$N(p,G)\$^{12}$C reaction is given in Figure 14. Here, the diffusion of 40 keV $^{15}$N in evaporation-deposited Ni was measured.(34) The nitrogen segregates to the surface and to the Ni–Ta interface at increased temperatures. The nitrogen distribution is very narrow and the broadening is due to experimental resolution at this depth. This is clearly seen at the measured depth profiles.

5 CONCLUSIONS

We have shown that PIGE offers a simple, sensitive and quantitative multielemental analysis technique. With
Figure 14 $^{15}$N profiles in evaporated Ni on Ta after annealing. The original profile is that of the 40 keV $^{15}$N implants (from Hirvonen et al. and Lappalainen and Anttila). The top layer of Ni is 370-nm thick. The measured $^{15}$N profiles show increased yields at the surface and at the Ni–Ta interface at increased temperatures (from Lappalainen and Anttila).

tunable accelerators and a good beam energy resolution, depth profiles can be obtained as deep as several micrometers, depending on the material and beam energy. The technique can be combined easily with PIXE and RBS for simultaneous additional information. The strength of PIGE is found particularly for very light elements where other techniques fail or experience difficulties. Sensitivities can reach the parts per million range, depending on the element of interest and on the matrix composition.

From the large number of analytical methods, activation analysis techniques are the only ones which are based upon nuclear reaction. The material sample studied is exposed to high-energy radiation which can be partly absorbed by a nucleus in the sample. Thus the nucleus is excited to a high energy level which can decay through quasi-prompt emission of a nuclear particle or photon. The product nuclide produced is mostly radioactive, and so emits delayed radiation. Both this and the aforementioned prompt radiation can be measured using appropriate radiation detectors. By evaluating the energy and the count rate of the particles detected, qualitative and quantitative analyses of the target material under study can be performed. Thus it is clear that elements only, not chemical species, can be determined directly. A large variety of particles can be used for activation, namely uncharged ones (neutrons, photons) or charged particles like protons, deuterons, tritons and even heavier ones. Mostly thermal neutrons from nuclear research reactors are used since this technique offers the highest average analytical sensitivity. During photon activation, the target nucleus is activated by photonuclear reaction. This is induced to “normal” material at high energies, usually not below about 10 MeV. The photonuclear reaction data of the elements suggest an activation energy around 30 MeV with respect to analytical sensitivity and interfering reactions, respectively. This energy is best achievable with bremsstrahlung sources like high-power linear accelerators or microtrons.
Favorable irradiation parameters are: 30 MeV electron energy at 100–150 μA mean electron beam current. With the help of suitable radiation spectrometers, e.g. high-resolution germanium detectors connected to appropriate pulse processing electronics, photon (γ or characteristic X-ray) spectra can be taken by which simultaneous multicomponent analyses can be carried out without chemical separations, sometimes even nondestructively. Moreover, partly extreme sensitivities can be achieved, and some elements can be analyzed whose determinations are difficult or impossible using other techniques, e.g. light elements like carbon, nitrogen, oxygen and fluorine. A further advantage is the relative freedom from blanks in many cases; after bremsstrahlung exposure, undesirable surface contaminants can be removed from the sample, and the recontamination that eventually occurs is inactive, and thus can be disregarded. Since the activation and measuring process is independent of the chemical status of the component studied, a large variety of matrices can be analysed. Photon activation has been applied in several areas including:

- geo- and cosmochemistry;
- environmental, biological and medical science;
- industrial product and high-purity material analysis;
- archaeological and forensic science;
- certification of reference materials.

The disadvantages of the method are common to all activation analysis techniques, e.g. the instrumental equipment costs. The cost of a high-performance germanium spectrometer is about US $30 000, and this does not include the permanent costs of maintenance and liquid nitrogen supply. Also, additional personnel qualifications are required for radioactive laboratory work. Finally, the handling of radioactive waste unavoidably produced during activation analysis might be problematic in some cases.

1 INTRODUCTION

1.1 Analytical Use of Electron Accelerators

Electron accelerators have been used not only for nuclear and particle physics but also in many other areas, such as in material, biological, geological and archeological sciences. In the analytical use of electron accelerators, photons such as synchrotron radiation and bremsstrahlung induced by high-energy electrons have been used more frequently than an electron beam itself.

Synchrotron radiation is generated by high-energy electrons circulating in the synchrotron. Synchrotron radiation energy is distributed continuously covering the infrared (IR) to X-ray region and interacts with molecules or atoms. In particular, the X-ray region of synchrotron radiation has been applied extensively to the field of analytical science using X-ray photoelectron spectroscopy (XPS), extended X-ray absorption fine structure (EXAFS), and X-ray fluorescence (XRF); these methods are useful to determine elements and their chemical states. Recently, many facilities using electron storage rings have been constructed for the exclusive use of synchrotron radiation.

However, bremsstrahlung is radiated in a forward direction of the electron beam when the electron is decelerated by Coulomb interactions in a material. Bremsstrahlung has a continuous energy distribution with a maximum energy equal to the electron acceleration energy. As the photon energy is significantly higher than that of synchrotron radiation the bremsstrahlung photon interacts with the nucleus. The cross-sections of photonuclear reactions are about a hundred times larger than that of nuclear reaction induced by electrons of the same energy. Therefore, bremsstrahlung from high-energy electrons can well be used for radioisotope production and particularly for activation analysis. Usually, photon activation analysis (PAA) is carried out using an electron linear accelerator or a microtron which can supply mean electron beam currents of some tens to hundreds of microamperes at energies between 6 to say 60 MeV.

1.2 Principle of Photon Activation Analysis

In PAA, unknown samples are irradiated with high-energy photons. Then, radionuclides produced by photonuclear reactions in the sample (the (γ,n)-type reaction occurs most probably; see below, section 2) are identified by their radiation emission energy, and the intensity of radioactivity is measured. Each radionuclide represents an element originally present in the sample studied, and the intensity of radioactivity is proportional to the abundance of this element.

In general, unknown samples and comparative reference standards are irradiated simultaneously or sequentially, equipped with flux monitors. After correction of the activating photon flux received by the sample and the standard, respectively, the contents of the components of the sample can be calculated by the specific activity ratios of the sample and the comparative standard. Usually, a γ-ray spectrum of sample is measured with a high-resolution spectrometer as described below (see section 1.2.2). In the spectrum, the elements present in the sample are represented by respective peaks whose areas are proportional to the radioactivity of the element to be determined. The peak area ratio of the sample and the standard is commonly used for the calculation of the elemental content. In the following, the different radiation measurement devices commonly used in PAA are described briefly.
1.2.1 Scintillation Spectrometer

A scintillation detector consists of a large, cylindrical thallium (Tl)-doped NaI crystal which is shielded by aluminum housing (3 in. both in height and diameter being the standard size). Incident photon energy emitted from a radioactive sample is converted into visible light by the crystal. A photocathode plus photomultiplier (PM) tube is connected to the crystal. These convert the light flash into an electric pulse signal whose height is proportional to the absorbed photon-ray energy. These signals are processed further (amplified, reshaped and more) by a sequence of amplifiers (preamplifier, spectroscopy amplifier). The signals thus produced have values of several volts, depending upon the incident energy, are Gauss-shaped and short enough (4 µs in the normal approach) to enable undisturbed processing of high pulse frequencies, generated by higher activities of the measured material. The signals are processed further in a multichannel analyzer which produces a spectrum whose lines represent the respective energies emitted by the sample measured.

1.2.2 Coaxial Germanium Spectrometer

This device is used for high-resolution measurement of γ-rays. The basic set-up is similar to that of the NaI spectrometer described above. A high-purity germanium single crystal is applied instead the scintillation crystal plus PM tube. The other pulse-processing electronics are the same as described above. The resolution power exceeds that of an NaI spectrometer by about two orders of magnitude. Therefore, it is indispensable for the measurement of complex multicomponent spectra as mostly occur during instrumental multielement activation analysis.

1.2.3 Low-energy Photon Spectrometer

A low-energy photon detector (LEPD) is commonly used for detecting characteristic X-rays and γ-rays below 100 kV. The LEPD is made of a thin crystal of germanium (typically 10 mm thickness, 30 mm diameter). All the other devices in the spectrometer are the same as used in the coaxial spectrometer described above. The detection efficiency for X-rays is high, because X-rays are fully absorbed even by a thin crystal. Most of the photoactivation product isotopes of medium to heavy elements decay by electron capture (EC), because the (γ,n) reaction products are mostly neutron-deficient nuclides. EC decay is always accompanied by characteristic X-ray emissions whose energies are those of the respective decay products. The γ-ray spectra of medium to heavy elements are often more complex than the X-ray spectra, as shown by Segebade and Weise. Therefore, low-energy photon spectrometry offers a complementary method to γ-ray spectrometry. The LEPD detection sensitivities for 36 elements were compared with that of a usual Ge detector. For quantitative analysis, self-attenuation of X-rays in a sample should be always estimated by the factor

\[ F(E) = \frac{1 - \exp\left(-\mu(E)d\right)}{\mu(E)d} \]

where \( d \) is the sample thickness and \( \mu(E) \) is the total attenuation coefficient of the sample material at a given energy. Sato et al. carefully checked the self-absorption effect for the analysis of biological materials and the validity of the method was verified by analyzing several biological materials.

1.3 Short History of Photon Activation Analysis

The pioneering work on photonuclear reactions was done by Chadwick and Goldhaber in 1934. In this work, the photodisintegration of deuterons was induced by 2.62 MeV γ-rays from 208Tl as the excitation source. The radioisotope excitation method can only be applied to limited examples such as several isomers produced by (γ,γ')-reactions and the photodisintegration of deuterium and beryllium.

Since 1950, electron accelerators have been constructed in many research institutions. These primarily served nuclear physics purposes, but an intense systematic study of PAA also began. In 1954, Basile et al. used a betatron for the determination of oxygen in organic acids. In the beginning, PAA was recognized as an analytical tool for light elements such as C, N and O, which cannot be determined by neutron activation analysis (NAA) using nuclear reactors.

First, Geiger-Müller counters were used for product nuclide radiation counting. In the 1940s, the energy resolution power of scintillation crystal detectors was recognized. Mostly Tl-doped NaI crystals were used for γ-counting, and they are still used for special applications e.g. light element analysis.

Since the beginning of the 1960s, high-resolution γ-ray spectrometry developed dramatically with the introduction of the Ge-based semiconductor detector, the multichannel analyzer and, somewhat later, the computer. In activation analysis, multielement analysis frequently can be performed easily without chemical separation. PAA has been extensively applied to a large variety of materials as a complementary tool for NAA, and it has been recognized that PAA is suitable for multielement analysis of geological, biological and environmental materials. The analysis of light elements in highly purified materials has been also very important in the field of material science and technology and will be of urgent interest also in the future.
Electron accelerators of comparatively low energy (a few tens of megaelectron-volts) and high power (a few kilowatts) have been used for PAA. However, a limited number of electron accelerators suitable for PAA are available for analysts since modern accelerators are designed for the production of much higher energies to primarily meet the demands of nuclear and particle physicists.

1.4 Textbook and Data Collections for Photon Activation Analysis

In 1972, Engelmann\(^6\) introduced PAA in his book *Advances in Activation Analysis*, in which the principle of PAA and the application to light element analysis were explained in detail. *Photon Activation Analysis* by Segebade et al.\(^7\) is a comprehensive textbook of PAA, containing 1206 references and many useful tables, such as a list of usable and competing photonuclear reactions and a list of \(\gamma\)-rays and X-rays. Kushelevsky\(^8\) presented a short guide of PAA in *Activation Analysis*, where the principles and applications of the method are concisely summarized.

Toms\(^9\) compiled the photonuclear reaction products and their \(\gamma\)-ray energies whilst Williams et al.\(^{10,11}\) collected \(\gamma\)-ray spectra of 40–44 MeV photon activation products. Lutz and Segebade\(^{12}\) published a two-dimensional (half-life versus \(\gamma\)-ray energy) map of photonuclear reaction products and Kato\(^{13}\) obtained sensitivities of 71 elements in PAA using 30 MeV bremsstrahlung. These basic data have been very helpful for users of PAA.

2 PHOTONUCLEAR REACTION

2.1 Characteristics of Photonuclear Reactions

A photonuclear reaction is the interaction between a nucleus and photon. The cross-section of a photonuclear reaction is mainly dependent on the probability of photon absorption. A schematic representation of the cross-section of the photon absorption is shown in Figure 1.\(^7\) The inelastic reaction which is expressed by \((\gamma,\gamma')\) can be induced by the irradiation of photon energies even below a few mega electron volts and target nuclides are excited from the ground state to some isomer levels. The cross-section integrals of \((\gamma,\gamma')\) reactions are very small, and only a few radioisotopes which are useful for PAA are produced. A photonuclear reaction is usually characterized by the “giant dipole resonance” or “giant resonance”, because this type of reaction has the largest cross-section among several types of photonuclear reactions. When the wavelength of the photon becomes similar to the diameter of nucleus, the photon can be absorbed by the target nucleus through the electric dipole resonance mechanism with a high degree of probability. This phenomenon is interpreted by the fact that a collective oscillation of all protons against all neutrons is induced by the electromagnetic wave. The maximum cross-section region is located at about 14 MeV for heavy elements to about 25 MeV for light elements. After photon absorption, one or two neutrons and/or protons or higher-order particles can be released because the binding energy of one nucleon is about 10 MeV. At about 60 MeV where the wavelength approximately equals the diameter of the deuteron, a neutron–proton pair in a nucleus is likely to absorb the photon. As the result of this reaction, called a “quasi-deuteron reaction”, a proton and neutron pair is emitted. In this energy region, two or more nucleons can also be released from the target nucleus by a direct process and many kinds of reaction products are formed. The cross-sections of the direct process are much smaller than that of the \((\gamma,n)\) reaction of the giant resonance region. Above 150 MeV, the total photoabsorption cross-section increases again because of the photo-meson production. As the spallation and fragmentation reactions are also induced, various reaction products are produced. However, the latter two types of photoreaction are not suitable for analytical purposes, but rather have to be considered as sources of interference.

2.2 Bremsstrahlung for Photon Activation

Several radioisotopes (e.g. \(^{124}\)Sb) were used as \(\gamma\)-ray excitation sources and applied to the analysis of deuterium, beryllium and several isomeric states. Photon fluxes from

![Figure 1](image-url)
PHOTON ACTIVATION ANALYSIS

such radioisotopes are usually not sufficient for practical elemental analysis purposes.

Bremsstrahlung is used preferably for activation in PAA. Bethe and Heitler\(^{(14)}\) theoretically discussed the radiation loss of electrons. Interaction between electrons and matter can be explained as follows. For low atomic number \((Z)\) target material and low-energy electrons, the major partition of energy loss is due to ionization. For high-\(Z\) target and high-energy electron, radiation energy loss is increased. As the radiation loss is proportional to \(Z^2\), elements with higher atomic number more efficiently produce bremsstrahlung. Radiation length is defined as the thickness in which the energy of the electron is reduced to \(1/e\) of its incident energy. The radiation lengths of air, aluminum and lead are 304 \(\text{m} \) (36.7 \(\text{g cm}^{-2}\)), 8.9 \(\text{cm} \) (24.0 \(\text{g cm}^{-2}\)) and 5.6 \(\text{mm} \) (6.37 \(\text{g cm}^{-2}\)) respectively. The cross-sections of ionization and radiation loss become equal at a critical energy which is about \(800/Z\ \text{MeV}\), where \(Z\) is the atomic number of the target. Therefore radiation loss becomes predominant for electrons above 10 \(\text{MeV}\), when a heavy element, e.g. platinum, is used as target material.

In the case of a thin target, bremsstrahlung is radiated strongly to the forward direction, i.e. the direction of the incident electron beam. A thick target is used in practice for activation analysis. In this case, the angular distribution of bremsstrahlung is broadened, and the percentage of low-energy photons increases because of the multiple scattering of the electron in a thick target. Figure 2 shows the calculated photon flux for electron energies of 25, 30 and 35 \(\text{MeV}\) and a mean electron beam current of 100 \(\mu\text{A}\).\(^{(15)}\) The spectrum of bremsstrahlung is calculated by Schiff’s equation.\(^{(16)}\) The tungsten target is 6 mm (two radiation lengths) thick, which is the range of 35 \(\text{MeV}\) electrons (thus, all incident electrons are absorbed). The spectrum is integrated over 5° from the direction of the electron beam.

In PAA, the most suitable irradiation energy is 20–30 \(\text{MeV}\) because the radiated bremsstrahlung spectrum covers the giant resonance region of most of the nuclides. Under such irradiation conditions, reaction products induced by the \((\gamma,\text{n})\) and \((\gamma,\text{p})\) reactions can be conveniently used for quantitative element determination.

### 2.3 Photonuclear Reaction Yield

In PAA, the reaction yield is used for the estimation of sensitivity of the pertinent element and the magnitude of nuclear interference. When a photonuclear reaction is induced by the irradiation of bremsstrahlung of a certain maximum energy the photonuclear reaction yield \(Y\) can be derived by the integral in Equation (1) by using the bremsstrahlung spectrum and the excitation function for the relevant reaction,

\[
Y = N_0 \int_{E_{\text{th}}}^{E_{\text{max}}} \sigma(k) \Phi(k, E_{\text{max}}) k^{-1} \, dk
\]  

where \(N_0\) is Avogadro’s number, \(E_{\text{th}}\) is the threshold energy for the reaction, \(E_{\text{max}}\) is the bremsstrahlung maximum energy, \(\sigma(k)\) is the cross-section in square centimeters per nucleus, and \(\Phi(k, E_{\text{max}})/k\) is the number of photons at a given energy \(k\). If the bremsstrahlung spectrum is normalized to 1 roentgen and a target amount of 1 mole is used, a yield can be obtained per mole per roentgen.

When equivalent quanta, \(Q\), are introduced, the yield per equivalent quanta for the given reaction, \(\sigma_Q\), is given by Equation (2),

\[
\sigma_Q = Q^{-1} \int_{E_{\text{th}}}^{E_{\text{max}}} \sigma(k) \Phi(k, E_{\text{max}}) k^{-1} \, dk
\]

where \(Q\) is given by

\[
Q = \int_0^{E_{\text{max}}} \Phi(k, E_{\text{max}}) \, dk
\]
According to the definition, \( Q \) is a hypothetical number of photons per second per square centimeter assuming maximum energy of all photons.

The general feature of a photonuclear reaction yield at the bremsstrahlung maximum energy of 30 MeV is shown in Figure 3 where the yields of various types of photonuclear reactions are plotted against the atomic number. The yields (\( \text{mol}^{-1} \text{R}^{-1} \)) of \((\gamma,n)\), \((\gamma,2n)\) and \((\gamma,3n)\) reactions increase with mass number. The \((\gamma,p)\) reaction shows maximum yield at atomic number 20 and decreases with atomic number. In the case of higher-order charged particle emission reactions, yield curves show a similar shape as that of \((\gamma,p)\) reaction.

The reaction yields of the \((\gamma,n)\), \((\gamma,p)\) and \((\gamma,\alpha)\) reactions were measured with 20 MeV bremsstrahlung irradiation. The difference of the yields between 20 and 30 MeV are small. The reaction yields were also measured systematically at 60 MeV irradiation. The yields of the single particle emission reactions, such as \((\gamma,n)\), \((\gamma,p)\) and \((\gamma,\alpha)\), are almost equal to the results of 30 MeV irradiation. The yields of \((\gamma,2n)\), \((\gamma,3n)\), \((\gamma,4n)\), \((\gamma,pn)\) and \((\gamma,\alpha n)\) reactions are remarkably higher. The \((\gamma,2p)\) reactions are observed for several light elements. The emission of more particles, up to nine, was observed at 60 MeV.

To observe the dependency of the photonuclear reaction yield upon energy and mass number, the functions of the yield \((Q; \text{mb})\) for the \((\gamma,n)\), \((\gamma,p)\) and \((\gamma,\alpha)\) reactions are shown in the form of two-dimensional graphs in Figures 4, 5 and 6. In these figures, \(x\)- and \(y\)-axes show the target mass number and bremsstrahlung maximum energy.

3 ANALYTICAL APPLICATION OF PHOTON ACTIVATION

3.1 Conditions of Photon Activation Analysis

At constant photon flux during irradiation, radioactivity induced in an element to be determined can be calculated as shown in Equation (4):

\[ A = \frac{\omega N_0 \theta}{A W} \sigma_{Q} [1 - \exp(-\lambda t)] \]  

where \( w \) is the amount of element, \( \theta \) is the isotopic abundance of the target isotope, \( AW \) is the relative atomic mass of element, \( \sigma_{Q} \) is the yield (cm² per equivalent quanta), \( Q \) is the flux density (equivalent quanta cm⁻² s⁻¹), \( \lambda \) is the decay constant of the induced radioisotope, and \( t \) is the irradiation time.

In order to produce bremsstrahlung efficiently, metals of high \( Z \) and high melting point, such as platinum and tungsten, are recommended as a converter material. Electron energy which is higher than about 15 MeV is indispensable to induce giant resonance reactions. Beam currents of several tens to hundreds of microamperes are necessary to induce radioactivity giving sufficient detection sensitivity. Betatrons and synchrotrons are not suitable for PAA due to their low beam currents. In Van de Graaf accelerators, beam current is in the microampere region, but the acceleration energy is low. However, many types of electron linear accelerators and microtrons are suitable for PAA.

As an example, consider the induced radioactivity estimated using Equation (1). The equivalent quanta obtained under the irradiation conditions mentioned above are about \( 10^{14} \) cm⁻² s⁻¹. The yield of \((\gamma,n)\) reaction is around 100 mb (10⁻²⁵ cm²²) for elements in the relative atomic mass region of around 100 (say molybdenum through silver). When 1 µg g⁻¹ of an element in a sample of 100 mg is analyzed, the number of target nuclides is about \( 10^{14} \). After irradiation for a duration equal to 1/10 of the half-life of the radioisotope, induced activity is about \( 10^5 \) disintegrations s⁻¹. When the detection efficiency is 1%, 10 counts s⁻¹ can be obtained. To obtain \( \gamma \)-ray peak counts within a counting error of 1%, a counting time of 1000 s is necessary at least. Therefore, it seems to be efficient to simply increase the irradiation time, flux, sample mass, detector efficiency and counting time. However, in the instrumental approach (analysis without radiochemical separation), the detection limit cannot always be improved so simply since the background activity might also be increased. The choice of irradiation energy and the cooling time is more effective to attain better detection limits.

Sensitivity data have been published which were obtained for several conditions of irradiation and...
3.2 Characteristics of Photon Activation Analysis

Since PAA is a complementary method to the more familiar NAA, the characteristics of both are compared in the following.

3.2.1 Transmittance of High-energy Photons

As high-energy photons can penetrate and activate mostly without notable matrix effects, PAA is suitable for bulk analysis of various kinds of materials and for simultaneous irradiation of several samples. The photon flux decreases with distance from the conversion target. Moreover, the bremsstrahlung beam exhibits a sharp flux density gradient perpendicular to the beam axis. Thus the activating radiation doses of samples and comparison standards should be monitored.

3.2.2 Systematic Trend of Photonuclear Reaction Yields

The $(\gamma,n)$ reactions are mostly utilized in PAA. As shown in Figures 3 and 4, the threshold energies of the $(\gamma,n)$ reactions are about 10 MeV for heavy elements and about 20 MeV for light elements. The $(\gamma,n)$ reaction yields of heavy elements are up to two orders of magnitude higher than those of light elements at the bremsstrahlung maximum energy of 30 MeV. However, light elements are usually major components and heavy elements exist at trace levels in natural products. As the radioactivity induced in an element is roughly proportional to the product of the yield and the abundance of the pertinent element, the differences in radioactivities induced in the light and heavy element fractions are frequently of the same order of magnitude. Such a systematic trend of photonuclear reaction yields gives the well-balanced sensitivities for the instrumental analysis of natural samples.

3.2.3 Interference by Self-shielding Effect, Matrix Activity and Fission Products

In NAA, the self-shielding effect and intense radioactivity sometimes interfere with trace element analysis, as there are several nuclides which have anomalously large neutron capture cross-sections. Typical examples of self-shielding are Cd and B. In NAA, after neutron exposure, $^{24}$Na, $^{32}$P and $^{82}$Br are major activities in biological materials and $^{56}$Mn and $^{24}$Na are major activities in rock, dust, soil and related samples because of their large neutron activation cross-sections. Rare-earth metals such as Eu and transition metals such as Co also lead to intense radioactivities and self-shielding. In PAA, such a self-shielding effect is mostly negligible, and the problem of matrix activity is not so frequent because of the penetrability of bremsstrahlung and, respectively, the systematic character of photonuclear reaction yields as mentioned above.

When U and/or Th are present in a sample in large amounts, neutron-induced fission products often interfere with the analysis of medium to heavy elements because some of the nuclides formed by fission are the same as those used for NAA of another element. A respective interference might also occur in PAA, but not to the extent as in NAA.

In NAA, the determination of Mg, Ti, Ni, Y, Zr, Nb, I, Tl, Pb and the light elements is very difficult. However, these elements are easily determined by PAA because photonuclear reaction products of these elements have suitable nuclear characteristics for photon spectrometry. More than 30 elements in geological and environmental samples can be determined instrumentally. To reduce radioactivities from light elements and to improve the signal-to-background ratio for heavy elements, 20 MeV irradiation is sometimes preferable to 30 MeV irradiation. Most of the medium to heavy elements can be determined at concentration levels of micrograms per gram and below.

3.2.4 Characteristics of the $(\gamma,n)$ Reaction Products

Radioisotopes induced by the $(\gamma,n)$ reaction decay with positron emission and/or EC in the most cases. Several light elements, such as carbon, nitrogen, oxygen and fluorine, lead to purely positron-emitting nuclides. These can be determined by the coincidence counting method (see below, section 4.1). Many of the $(\gamma,n)$ products from medium to heavy elements decay by EC. In EC decay, the detection of characteristic X-rays of the decay product is convenient for analytical purposes. Low-energy photon spectrometers (see above) are useful to detect characteristic X-rays and low-energy $\gamma$-rays.

4 ANALYTICAL PROCEDURES

4.1 Procedure for Light-element Analysis

As mentioned above, the photonuclear activation products of some light elements like C, N, O and F are pure positron emitters without any characteristic photon emission. The annihilation photon quanta ($E = 511$ keV) produced through reaction of positrons with electrons in close vicinity can be measured most favorably with a pair of $\gamma$-ray detectors facing one another and electronically switched in coincidence.\(^{(6,7)}\) Since the annihilation
PHOTON ACTIVATION ANALYSIS

quanta, each representing the rest mass of an electron, are emitted from the source at an angle of 180°, the pulse processing electronic system is set up to exclusively count quanta coincidently absorbed in both detectors. Thus, radiation background is suppressed to a great extent. Because the photon energy is unspecific, detectors. Thus, radiation background is suppressed to a great extent. Because the photon energy is unspecific the activation product (\(^{11}\)C, \(^{13}\)N, \(^{16}\)O, \(^{18}\)F respectively) usually has to be separated from the sample matrix after bremsstrahlung exposure. The different appropriate radiochemical separation procedures are described in detail in the literature.\(^3,4\) Heat extraction of radiocarbon, radionitrogen and radiooxygen followed by collection of the respective radiofractions with appropriate agents, as well as vapor distillation of radiofluorine, are utilized mostly. The radiochemical purity of the separated fraction is checked by recording a decay curve during photon counting and comparing the half-life thus obtained with the literature value. Analyses without chemical separations are possible in exceptionally favorable cases only.

The practical analytical procedure typically might be as follows: The analytical sample is prepurified and wrapped in aluminum foil. The comparison standard (usually the pure element, e.g. graphite in the case of carbon analysis, or a stoichiometrically well-determined compound) is also wrapped, and both samples are stacked in an irradiation container, e.g. an aluminum rabbit. This is then transported pneumatically to the irradiation position. The exposure period is adjusted according to the respective half-life and to the expected concentration to be determined. After irradiation, the rabbit is transported back into the laboratory where the samples are unpacked, taken out of the aluminum foil and eventually etched with a cleaning agent to remove surface contaminants. Thereafter, the sample is subject to radiochemical separation. Then the collecting substance containing the radionuclide to be measured is brought into the counting position between the detector pair, followed by multiple countings at a fixed cycle. Counting cycle and data acquisition are performed by a personal computer. The comparison standard is then treated likewise, eventually omitting the cleaning step. The element content is then calculated by comparison of the integral count numbers of the sample and the standard, respectively.

4.2 Procedure for Multielement Analysis

Multielement analysis of natural samples by the comparative method is described as a typical case of PAA. The comparative method (see section 4.1) is mostly used in PAA. When a sample is irradiated together with a comparative standard that contains \(w_{\text{std}}\) of the element to be determined the unknown amount (\(w_x\)) of element in the sample is obtained by Equation (5):

\[
w_x = w_{\text{std}} \left( \frac{A_x}{A_{\text{std}}} \right) \left( \frac{\phi_{\text{std}}}{\phi_x} \right)
\]

where \(A_x\) and \(A_{\text{std}}\) are the activities induced from the element to be determined and \(\phi_x\) and \(\phi_{\text{std}}\) are fluxes of bremsstrahlung irradiated on the sample and the comparative standard respectively.

Usually, the \(\gamma\)-ray peak area ratio of the sample and the standard is used instead of the activity ratio \((A_x/A_{\text{std}})\). In this case, the counting geometry (such as the shapes of sample and standard, the distance from sample and detector) must be equal. As the radioactivity decays according to its half-life after irradiation and also during measurement, the radioactivity of sample and standard should be normalized to the same time, usually the end of irradiation. When the obtained peak count number (C) is normalized to the end of irradiation, the initial activity \((A)\) is calculated by Equation (6):

\[
A = \frac{C \lambda}{\exp(-\lambda t_c)\left[1 - \exp(-\lambda t_m)\right]}
\]

where \(\lambda\) is the decay constant \([\ln(2)/t_{1/2}]\) for the radioisotope, \(t_c\) is the cooling time after irradiation, and \(t_m\) is the measuring time.

4.3 Sample Preparation, Standard and Flux Monitoring

For the comparative method, a standard containing a well-known amount of each component to be analyzed must be available. This might be a multielement or a single element comparator. It is desirable that such a standard and samples have similar elemental compositions. These materials should be prepared under strictly controlled conditions following preparation procedures which enable maximum accuracy of the respective element concentrations. Certified reference materials (CRMs) should not be used for highly precise concentration calculations, but rather as materials analysed for quality control of the obtained results, the accuracy in particular.

As various kinds of CRMs are issued by many organizations in the world, a standard suitable for nearly each analytical purpose can be chosen. These CRMs are analyzed by several analytical methods at several laboratories. However, most of these certified values are averaged values with standard deviations. Usually only limited numbers of elements are certified. There are several examples where the concentration of the element to be determined is not certified or its concentration is largely different from that in the sample. In order to avoid this, two or more CRMs can be used for cross-checking. When natural products are used as CRMs, homogeneity and stability should be checked carefully. Also limited
amounts of CRMs have been supplied. In most cases the use of CRMs as comparators is not recommended, since high-precision results as required in certification analyses cannot be expected.

Laboratory standards have been useful to solve the above problems. A filter paper doped with several standard solutions of elements to be determined is often used in NAA. This method cannot be recommended for PAA because a small amount of residual acid might decompose the cellulose paper during irradiation. Moreover, the homogeneity of filter paper is questionable. Phenol–formaldehyde resin\(^\text{25}\) and gelatine\(^\text{26}\) were used as the base materials for activation analysis of biological materials. An artificial standard of polyacrylamide gel matrix was also developed by utilizing the copolymerization reaction of acrylamide in a mixed solution containing the appropriate amounts of elements.\(^\text{27}\) Polyacrylamide has high tolerance for radiation and a similar matrix composition to biological materials. For the analysis of rock samples, multielement solution was gelatinized by hydrolysis of tetraethyilsilicate.\(^\text{28,29}\) As the gelatinization takes place in acidic conditions, most of the standard solution of metals can be used directly. Silica gel has high stability for irradiation. The elemental abundance in such synthetic standards is easily and accurately obtained as the weight ratio of the added amount of element to the final weight of gel, and elemental composition can be adjusted freely according to samples to be analyzed and elements to be determined. The homogeneity of these standards is usually satisfactory because the mixed solution containing several elements is solidified as is.

As photon flux and energy spectrum show pronounced gradients, bremsstrahlung irradiated on each sample should be monitored individually. To estimate flux, sample and standard are stacked alternately or irradiated with flux monitors. The accuracy of the former method is good because the specific activity of each element in the standard is plotted against the irradiation position and the specific activity induced in the sample can be estimated. However, the measurement of samples and standards irradiated is very time-consuming. In the latter method, the monitor reaction data are largely different from the reaction for analysis of each element. Therefore, it is recommended to choose the monitor reaction that has a similar excitation function to the reaction for analysis, and a product radioisotope that has a half-life similar to those of the radioisotopes to be determined.

4.4 Irradiation

An example of an irradiation set-up\(^\text{30}\) is shown in Figure 7. The beam profile can be observed with a thin beryllium oxide disk of 0.2 mm in thickness and the beam position is precisely adjusted with a platinum position monitor made up of a thin wire and a small flat tip connected to an electronic microammeter. The platinum tip is positively charged by secondary electron emission when hit by the electron beam. Therefore, the beam position can be pointed exactly to the center of sample by scanning for the maximum current of the microammeter. The beam intensity is indirectly monitored with a ferrite-core-loaded toroidal coil coupled with a current integrator after rectification, because electric current is induced on the toroidal coil when a pulsed beam is passing through the core. This core monitor has been calibrated with a pulse generator. The induced pulses are also monitored

![Figure 7 Schematic drawing of the irradiation system. (Reproduced by permission of Akademica Kiado, Budapest.)](image-url)
with an oscilloscope. Four pieces of platinum plate of 0.5 mm thickness are placed inside the sample holder to serve as the conversion target. The converter and sample are cooled with water to avoid melting of materials caused by high incident beam power. The beam power, which is the product of electron energy and average beam current, turns to heat finally. In this facility, irradiation, for activation analysis has usually been performed at 30 MeV electron energy and 150μA average current. Hence, 4.5 kW of beam power is focused within a diameter of a few millimeters.

Bremsstrahlung does not cause such significant radiation damage on the sample. Electrons penetrating the converter cause radiation damage and local heating which creates severe problems especially for biological samples. To reduce effects caused by penetrating electrons, a graphite block has been inserted between the converter and sample. Light elements absorb electrons efficiently without reducing the flux of bremsstrahlung from the converter considerably. Also, a bending magnet placed behind the converter to deflect electrons passing through the converter has been applied. In this case, samples should be kept at a good distance from the converter to avoid unwanted electron bombardment. Another possibility to avoid electron-induced damage is to use a thick target which absorbs all electrons (see above).

Secondary neutrons are mainly emitted from the converter and also from surrounding materials. These neutrons are predominantly induced by photonuclear reactions in the giant resonance region. It is known that energy spectra of photoneutrons are predicted by the statistical model of the nucleus, and the angular distribution is mainly isotropic. Photoneutrons are retarded by the collision with surrounding materials and thermalized by water and other light material in the vicinity. Such neutrons cause the (n,γ), (n,p) and (n,α) reactions in a sample.

The spatial distributions of bremsstrahlung and photoneutrons are shown in Figure 8. Figure 8 shows the results of Pt (2 mm) plus graphite (10 mm) and Pt (2 mm), W (3 mm) and graphite (10 mm). The solid lines show the distribution of activity of 196Au induced by the 197Au(γ,n)196Au reaction which corresponds to the flux of bremsstrahlung. In Figure 8, the spatial distribution of neutrons is drawn by dotted lines, according to the 198Au activity induced by the 197Au(n,γ)198Au reaction. According to the result of Engelmann,6 the best thickness of

![Figure 8](image-url)
platinum converter to induce \((\gamma, n)\) reactions is 3 g cm\(^{-2}\) at 30 MeV and 4.5 g cm\(^{-2}\) at 45 MeV. As the thickness of 2 mm is 4.3 g cm\(^{-2}\), the converter thickness presented in Figure 8(a) is suitable for activation. In this case, electron energy is reduced by half of the initial energy. The target combination of Figure 8(b) is used for the irradiation of biological materials. The additional converter of 3 mm thick W plate can reduce the initial electron energy by a factor of six, and the graphite block of 10 mm in thickness can fully absorb electrons passing through the converter. As this graphite block absorbs only 3 to 4% of photons at the energy of 10 to 30 MeV, photon flux is not suppressed significantly. As shown in Figure 8(b), the bremsstrahlung beam produced by the converter of 5 mm in thickness is broadened, and the photoelectron flux is increased. The full widths at half-maximum of bremsstrahlung induced by 2- and 5-mm-thick converters are 12 and 16 mm, respectively, directly behind.

PHOTON ACTIVATION ANALYSIS

the graphite block. Through quasi-elastic scattering the photoneutrons are also distributed behind the graphite block. The spatial distribution and neutron thermalization are influenced by the irradiation conditions. To estimate the interference caused by photoneutrons it is recommended that neutron monitors be applied adjacent to the samples during each radiation cycle.

High irradiation energy is preferable to obtain better sensitivity. However, as several types of photonuclear reactions are increasingly induced at the incident electron energy above 30 MeV, nuclear interference problems arise at higher irradiation energy.

4.5 Measurement and Evaluation

The elements and nuclear data for PAA of typical natural samples are listed in Table 1. Since each radioisotope has a specific half-life, detection sensitivity and signal-to-background ratio, which depend upon both matrix activity and radioactivity to be analyzed, are strongly decay-time dependent. Figure 9 shows the time dependency of detection limits of nine elements in coal fly ash (NIST Standard Reference Material (SRM) 1633a) irradiated at 25 MeV for 2 h. The detection limit is defined as the concentration of element which yields the count number equal to 3σ of background counts under pertinent γ-ray photopeak. As shown in Figure 9, the detection limit strongly varies with cooling time. For multielement analysis of natural samples, γ-ray spectra of samples should be measured several times at appropriate intervals after irradiation. In Figure 10, the detection limits of 26 nuclides are plotted against a suitable cooling time in the case of coal fly ash quoted above. The degree of interference from γ-ray overlapping also changes according to the half-lives of pertinent nuclides. Therefore, the cooling time should be carefully adjusted in order to analyze each element under the best possible conditions.

As a result, typical γ-ray measurements for the analysis of the type of natural products studies are performed preferably in the following periods: (1) a few minutes after irradiation for K, Cl; (2) a few hours after irradiation for Ti(47Sc), Sc, Fe, Sr; (3) a few days after irradiation for Mg, Ca(43K), Ti(48Sc), Ni, Ba, Pb; (4) 1 week after irradiation for Ca(47Ca), Zn(67Cu), Cs, Zr, Mo, Sb, U; and (5) several weeks after irradiation for Na, Ti(46Sc), Cr, Mn, Co, Zn(65Zn), As, Rb, Nb, Y, I, Ce, Tl. Two or more radioisotopes are available for the determination of several elements, e.g. Ca, Ti and Zn.

5 INTERFERENCE MANAGEMENT

5.1 Interference Reactions

In PAA, a radioisotope used for determination can be produced by another element. The interference reactions have been discussed by Kato et al.,(20,21) Williams and Hislop,(23) Segebade et al.(33) and Miyamoto et al.(34)

Typical examples of nuclear interference are listed in Table 2. For example, 55Mn(n,p)55Mn and 52Cr(n,γ)51Cr reactions are used for the determination of Mn and Cr. However, 54Mn and 51Cr can be produced by 56Fe(p,γ)54Mn and 56Fe(α,γ)51Cr reactions from Fe. The degree of interference is strongly dependent upon the irradiation conditions and, in particular, the Mn/Fe and Cr/Fe abundance ratios. Hence, when natural materials are analyzed the interference of Cr and Mn might be crucial since usually Fe is in significantly higher concentrations than the former elements in these materials. For the determination of Na(23Na) through 23Na(n,γ)22Na the analytical reaction suffers interference from 24Mg(p,n)23Na and 27Al(α,γ)22Na. The interferences from Mg and Al should be checked as well. The interference reactions are always accompanied by charged particle emission. As these reactions are suppressed by the nuclear Coulomb barrier, interference reactions are not so severe for heavier elements.

Photoneutrons also cause interference problems for the analysis of several elements. For example, 24Na from 23Mg(γ,p)24Na for the determination of Mg and 56Mn from 57Fe(γ,p)56Mn for the determination of Fe suffer interference from 23Na(α,γ)23Na and 55Mn(γ,γ)55Mn, respectively. The distribution of photoneutrons is critically dependent on the irradiation condition and set-up as shown in Figure 8. Table 3 shows the weight ratio of the amount to yield the same activity from interference and analytical reaction. The weight ratios (yield of analytical reaction/yield of interfering reaction; calculated for equal element masses) were obtained at several irradiation positions using a 5 mm thick converter. The weight ratios in interference cases caused by photoneutron reactions decrease with the distance from the graphite block. Hence, the interference yields increase with the distance from the converter. In this interference case, the change of the weight ratio reflects the change of bremsstrahlung spectrum. This is due to the larger scattering cross-section of lower photon energies. In the case of photoneutron interference, the fast neutron flux rapidly decreases with the distance from the converter; consequently, the interference yield by slow neutrons becomes more significant than that by fast neutrons.

The nuclear reaction yields of the analytical reaction and the interference reaction were studied systematically. (21) The results are listed in Table 4 for the SRM orchard leaves (NIST SRM 1571) and in Table 5 for the geochemical reference sample JB-1 (basalt) issued by the Geological Survey of Japan. The magnitude of interference, expressed as the percentage of the activity induced by the interference reaction to the total activity, increases with the irradiation energy.

5.2 Peak Overlapping

Another type of interference is the spectral overlap of peaks whose energies are so close that the spectrometer cannot resolve them. These might be due to signals of different nuclides or one product nuclide whereby the former case is more critical than the latter. However,

<sup>a</sup> (Activity from interfering element)/(Total activity) × 100.
<sup>b</sup> Interference caused by photoneutron.

The use of doublet or multiplet peaks from one product nuclide should also be avoided. Typical examples for peak overlap interference by different nuclides are listed in Table 6. This type of interference mainly occurs during analysis of medium to heavy elements. To avoid the interference the difference of half-lives of product nuclides can be effectively used in the following cases: Co/Ca, As/Ca, Ti/Zn and Pb/Hg. However, this frequently entails excessive time consumption in the analytical task. On the other hand, if one nuclide emits two or more γ-ray energies, the peak ratio method can be applied to subtract the interfering peak area. Typical examples are Zn/Ga, Nb/Fe, Cs/I, I/Y and U/Ga. The latter method reduces the time consumption, but a greater analytical error is induced.

Nowadays the γ-ray overlapping interference is not so problematic due to the dramatic improvement of the energy resolution power of modern photon spectrometers; a modern Ge detector offers peak half-widths of 1.8 keV or less at 1333 keV (<sup>60</sup>Co). Moreover, several highly efficient peak deconvolution programs have been developed.

5.3 Other Errors

As mentioned in section 3.1, the induced radioactivity is proportional not only to sample mass but also to the cross-section and isotopic abundance of the sample components, flux of bremsstrahlung and saturation factor. In the case of γ-ray measurement, the peak count number obtained is dependent on the counting time, γ-ray branching ratio of radioisotope, detection efficiency of γ-ray and others. In the above factors, sample mass, irradiation time and counting period can be adjusted to reduce statistical errors and to improve precision and detection limit. However, the improvement of these factors is often restricted by the experimental conditions, such as number of samples and limited access to irradiation and measurement facilities. It is important to store the peak counts until the counting error becomes small enough.

Activation analysis includes the following steps: (1) sample preparation; (2) irradiation; (3) measurement; and (4) analysis. To improve accuracy, systematic errors

</table>
in each step should be checked carefully. Nuclear interference and \(\gamma\)-ray overlapping are avoidable, but some systematic errors, such as flux monitoring and counting geometry, cannot be cancelled out by quantitative methods. In the following section, the internal standard method, the standard addition method and the stable isotope dilution activation analysis used for highly accurate analyses are described.

6 QUANTITATIVE METHODS FOR QUALITY ASSURANCE

6.1 Internal Standard Method

The most reliable method for monitoring the activating flux received by a sample is the method using an internal standard because the flux monitoring component is inherent in both the sample and the comparative standard. This method was called the internal reference method by Tsai et al.\(^{35}\) and Yagi and Masumoto\(^{36}\) or the internal monitor method by Okada et al.\(^{37}\) in order to differentiate the slight change of the definition of each technique applied.

First, the comparative standard in which the abundance ratio \(K\) of the element \((a)\) to be determined and the internal standard element \((b)\) are accurately known is prepared. It is not necessary to know the absolute abundance of each element. The accurately weighed amount \((w_b)\) of the internal standard is added to the sample and mixed homogeneously. Then, appropriate amounts of the sample and the comparative standard are irradiated. The activity ratio of a pertinent element to the internal standard is measured for the sample \((R)\) and the comparative standard \((R^\ast)\), respectively, and the relevant equations are shown as Equations (7) and (8).

\[
R = \frac{A_a}{A_b} = \frac{(w_aN_0\beta_a/AW_a)\sigma_aQ[1 - \exp(-\lambda_a t_a)]}{(w_bN_0\beta_b/AW_b)\sigma_bQ[1 - \exp(-\lambda_b t_b)]} \quad (7)
\]

\[
R^\ast = \frac{A_a^\ast}{A_b^\ast} = \frac{(w_a^\ast N_0 \beta_a/AW_a)\sigma^\ast_a Q^\ast[1 - \exp(-\lambda_a t_a^\ast)]}{(w_b^\ast N_0 \beta_b/AW_b)\sigma^\ast_b Q^\ast[1 - \exp(-\lambda_b t_b^\ast)]} \quad (8)
\]

The sample weight and flux \((Q)\) are eliminated by introducing the activity ratio. Again, by including the ratio of the two activity ratios \((R^\ast/R)\) mentioned above, nuclear reaction yields, saturation factor, isotope abundance and relative atomic mass can be cancelled out. Using Equation (9), abundance ratios of the sample \((w_b/w_a)\) and the comparative standard \((K)\) are left.

\[
\frac{R^\ast}{R} = K \frac{w_b}{w_a} \quad (9)
\]

Therefore, the abundance of element \((a)\) can be calculated by Equation (10):

\[
w_a = Kw_b \left( \frac{R^\ast}{R} \right) \quad (10)
\]

When the ratio is obtained as the \(\gamma\)-ray peak area ratio, Equation (11) can be used.

\[
\frac{R^\ast}{R} = \frac{(C_a^\ast/\phi_0(y_a)\epsilon(y_a)\Omega^\ast)}{(C_b^\ast/\phi_0(y_b)\epsilon(y_b)\Omega)} \quad (11)
\]

where \(\phi(y)\) is the branching ratio of the \(\gamma\)-ray, \(\epsilon(y)\) is the detector efficiency at the \(\gamma\)-ray energy, \(\Omega\) is the solid angle of the measurement, and \(C\) is the peak area. The asterisk designates the standard. Finally, all these factors can be cancelled out by applying the double ratio. The double ratio can be expressed as two \(\gamma\)-ray peak area ratios.

In this method, it is only necessary to know the abundance ratio \((K)\) of the comparative standard and amount of internal standard element \((w_b)\) added to the sample, respectively. It is not necessary to weigh the sample and the comparative standard irradiated, to monitor the photon flux on sample and standard by the flux monitors, or to adjust strictly the geometrical condition of measurement, because this formula only needs the activity ratio. However, the latter statement is valid in limits only since the functions of counting efficiencies of the analytical signal and the internal monitor signal over the distance of the sample from the detector might differ. This difference can be significant particularly in the close vicinity of the detector.

It is essential that the irradiation energy for both the sample and the standard is the same. The difference of matrix effect between the sample and the comparative standard cannot be compensated by this method.

As to the comparison of the internal standard method with the single comparator method\(^{36}\) as frequently utilized in NAA: in the single comparator method, the same amount of an element \((a)\) to be determined and the comparator element \((b)\) are irradiated and the activity ratio of element \(a\) to \(b\) is measured in advance. The activity ratio \((C)\), which is regarded as constant, can be expressed as shown in Equation (12).

\[
C = \frac{(\theta_a/AW_a)\sigma_a[1 - \exp(-\lambda_a t_a)]}{(\theta_b/AW_b)\sigma_b[1 - \exp(-\lambda_b t_b)]} \quad (12)
\]

To determine an element in the sample, a sample and single comparator pair is irradiated simultaneously and the abundance of the element \((w_a)\) can be calculated by the activity ratio \((A_a/A_b)\), the amount of comparator \((w_b)\) and constant as in Equation (13):

\[
w_a = Cw_b \left( \frac{A_a}{A_b} \right) \quad (13)
\]
Although the quantitative equation of the internal standard method is analogous to that of the single comparator method, the principles of both methods are quite different from each other. The accuracy of the single comparator method is mostly unsatisfactory in PAA, because it is very difficult to keep the activity ratio constant. The energy spectrum for every irradiation and the beam current during one irradiation cannot be considered constant for every accelerator.

For highly pure materials, one of the main matrix components can be used conveniently as internal standard without adding an exotic element. This method was applied for the analysis of impurity or minor constituent in metals or alloys by Kato et al.\(^\text{35,37}\) If a matrix element (atomic number \(Z\)) leads to isotopes of \((Z - 1)\) or \((Z - 2)\) by the \((\gamma,p_{\text{xn}})\) or \((\gamma,\alpha_{\text{xn}})\) reactions, these radioisotopes can be used for internal standardization. Then, a \((\gamma,\alpha_{\text{xn}})\) product from neighboring elements (atomic number \(Z - 1\) or \(Z - 2\)) can be chemically separated together with isotopes of \((Z - 1)\) or \((Z - 2)\) induced from the matrix. As these internal standards chemically behave like the \((\gamma,\alpha_{\text{xn}})\) products from impurity, their activity ratio is always constant. Therefore, the unknown amount can be determined without correction of chemical yield.

When the internal standard is added to the sample, the following conditions are required: none or a negligibly small amount of internal standard exists in the sample; only one or two \(\gamma\)-rays emit from the internal standard; and \(\gamma\)-rays from the internal standard do not interfere with \(\gamma\)-rays to be analyzed. Sc, Y and Sm have been used routinely as internal standards for a variety of samples by Segebade et al.\(^{39}\) and Ce was used for the trace element analysis of aluminum alloys by Yagi and Masumoto.\(^{36}\)

To maintain maximum accuracy it is desirable that the half-life and \(\gamma\)-ray energy of the internal standard are similar to those of radioisotopes to be analyzed, and that the cross-section of the photonuclear reaction of the internal standard is similar to that of an element to be determined because the full energy spectrum of bremsstrahlung cannot be accurately monitored by using only one photonuclear reaction and also the photon flux tends to fluctuate in each irradiation.

### 6.2 Internal Standard Method Coupled with the Standard Addition Method

To achieve higher analytical accuracy without using any comparative standard and to compensate matrix effects arising from irradiation and measurement, the internal standard method coupled with the standard addition method has been proposed. This method was initiated by Lariaert et al.\(^{40}\) in NAA as the internal standard method. After Lariaert et al. applied it to NAA of minor elements in high alloy steels,\(^{41}\) Yagi and Masumoto\(^{42}\) revived it by the full use of high-resolution \(\gamma\)-ray spectrometry and a new sample preparation technique. In order to distinguish it from the method dealt with in the previous section, this method is called the internal standard method coupled with the standard addition method. In this section, the definition and characteristics of this method are described in some detail.

In this method, duplicate samples are taken. The accurate amount \((w_0)\) of element to be determined is added to one portion of sample. The sample and the standard addition sample are irradiated simultaneously and the activity ratios of the pertinent element and internal standard are measured for both sample \((R)\) and standard addition sample \((R^\ast)\).

The activity ratio of the standard addition sample can be expressed by Equation (14):

\[
R^\ast = \frac{A^\ast_b}{A^\ast_a} = \frac{[(w_a + w_0)N\beta_b/AW_a]Q[1 - \exp(-\lambda_{a}t_{b})]}{(w_bN\beta_b/AW_b)Q[1 - \exp(-\lambda_{b}t_{b})]}
\]

(14)

Then, by calculating the double ratio \((R^\ast/R)\), the amount of internal standard element \((w_b)\) is also cancelled out. As shown in Equation (15), a very simple relation is obtained.

\[
\frac{R^\ast}{R} = \frac{w_a + w_0}{w_a}
\]

(15)

The unknown amount of \(w_a\) is calculated using Equation (16):

\[
w_a = \frac{w_0}{[(R^\ast/R) - 1]}
\]

(16)

In this method, it is not necessary to know the amount of internal standard present in the sample \((w_b)\). Only the amount of element added to the sample \((w_0)\) is used for calculation. If an appropriate internal standard does not exist in the sample, the same amount of external element is added to the sample and the standard addition sample.

This method was applied to multielement analyses and one or more elements were used simultaneously as internal standards. For PAA of biological, geological and environmental samples, Na, Mg, Ca, Ti and Fe, usually inherent in natural samples, are useful internal standards because the concentrations of these elements are relatively high and half-lives and \(\gamma\)-rays of reaction products are convenient for the measurement. This method has been applied to PAA and charged particle activation analysis (CPAA) of biological materials,\(^{42-44}\) sediment,\(^{45,46}\) soil,\(^{47,48}\) fly ash\(^{49}\) and alloys.\(^{50-52}\)

The use of two or more internal standards is effective to cross-check the analytical results.\(^{53}\) The homogeneity of elements and internal standards in the sample and the standard addition sample is always checked by comparing with the standard deviations of activity ratios \((R^\ast\) and \(R)\).
If $\sigma(R^*)$ is always larger than $\sigma(R)$ of a certain element, only this element was not mixed homogeneously at the standard addition step. If $\sigma(R)$ is always larger than $\sigma(R^*)$ of a certain element, this element is not homogeneous in the sample itself.

This method combines the characteristics of the internal standard method and that of the standard addition method. In the standard addition technique, comparative standards are not necessary. This method can eliminate several systematic errors, which are involved in the comparative method, such as the matrix composition of sample, the geometrical conditions of irradiation and measurement, and the analysis of the $\gamma$-ray spectrum.

In order to check whether loss or contamination of an element is caused during sample preparation, another portion of sample is prepared in the same procedure as the standard addition sample without adding an element to be determined and the double ratio $(R^*/R)$ is also measured. When this ratio is <1, the pertinent element might be lost during the standard addition procedure. When this ratio is >1, contamination has to be considered. The analysis of CRMs by this method is useful to check the degree of interference reaction. If the content of one element is systematically higher than the certified value, the positive deviation indicates interference by other component(s) in the sample. As this method is capable of self-checking it is very useful for the analysis of reference materials.

### 6.3 The Stable Isotope Dilution Method

Stable isotope dilution activation analysis utilizes isotope analysis. For example, Ce has two stable isotopes, $^{140}$Ce (88.48%) and $^{142}$Ce (11.08%), which can produce $^{139}$Ce and $^{141}$Ce, respectively, by ($\gamma$,n) reactions. When an enriched isotope $^{142}$Ce is added to the sample, the activity ratio of $^{139}$Ce and $^{141}$Ce changes. The degree of the activity ratio change is relative to the abundance of Ce in the sample and the added amount of $^{142}$Ce. The conditions of this method are that the elements to be determined consist of at least two stable isotopes, and these two or more isotopes produce radioisotopes that can be detected separately by $\gamma$-ray spectrometry.

Stable isotope dilution activation analysis is performed using the following steps: the enriched isotope $j$ is used as a spike, in which the isotopic abundances $(\theta_i)$ of i and j are known; the enriched isotope $(w_s)$ is added to the sample; and the sample and the spiked sample are irradiated simultaneously. The activity ratio induced by two stable isotopes (i and j) is measured for the sample $(R_s)$ and the spiked sample $(R_m)$ using Equations (17) and (18).

$$R_s = \frac{A_i}{A_j} = \frac{(w_i\theta_i/\text{AW}_i)\sigma_j[1 - \exp(-\lambda_i t_i)]}{(w_j\theta_j/\text{AW}_j)\sigma_i[1 - \exp(-\lambda_j t_j)]} \quad (17)$$

$$R_m = \frac{A_{im}}{A_{jm}} = \frac{(w_i\theta_i/\text{AW}_i)\sigma_j[1 - \exp(-\lambda_i t_i)]}{(w_j\theta_j/\text{AW}_j)\sigma_i[1 - \exp(-\lambda_j t_j)]} \quad (18)$$

where the subscripts $x$, $s$, and $m$ indicate the sample, an enriched isotope and the spiked sample, respectively, $w_s$ is the weight of element in the sample, $w_i$ is the spiked amount of an enriched isotope, $\text{AW}$ is the relative atomic mass, $R$ is the activity ratio (isotope i/isotope j), and $\theta_i$ and $\theta_j$ are the isotopic abundances of isotopes i and j respectively.

Again the ratio of these activity ratios is used as shown in Equation (19):

$$R_m = \frac{(w_i\theta_i/\text{AW}_i) + (w_s\theta_s/\text{AW}_s)(w_i\theta_i/\text{AW}_i)}{(w_j\theta_j/\text{AW}_j) + (w_s\theta_s/\text{AW}_s)(w_j\theta_j/\text{AW}_j)} \quad (19)$$

Then, the equation is slightly simplified to Equation (20):

$$\frac{R_m}{R_s} = \frac{1 + (w_s/w_i)(\theta_i/\theta_s)(\text{AW}_s/\text{AW}_i)}{1 + (w_s/w_j)(\theta_j/\theta_s)(\text{AW}_j/\text{AW}_s)} \quad (20)$$

From Equation (20), the unknown amount ($w_s$) of element can be obtained using Equation (21):

$$w_s = \frac{w_i(\text{AW}_i/\text{AW}_s)\left(\frac{\theta_j}{\theta_i}\frac{(R_m/R_s) - (\theta_i/\theta_j)(\theta_i/\theta_j)}{1 - (R_m/R_s)}\right)}{1} \quad (21)$$

This equation was introduced by Masumoto and Yagi$^{(54)}$ in 1983.

When highly enriched isotopes can be used as spikes, the abundance ratio $(\theta_i/\theta_j)_{s}/(\theta_i/\theta_j)_{x}$ becomes much smaller than the activity ratio $(R_m/R_s)$. Then, a simple equation can be obtained, as shown by Equation (22):

$$w_s = \frac{w_i(\text{AW}_i/\text{AW}_s)\left(\frac{\theta_j}{\theta_i}\frac{1}{(R_c/R_m) - 1}\right)}{1} \quad (22)$$

As the unknown amount of an element can be determined by the activity ratio of two radioisotopes, the stable isotope dilution method is regarded as another type of internal standard method. In order to reduce error, the ratio $(R_m/R_s)$ should preferably range from 0.3 to 0.7.$^{(55)}$

In PAA, this technique was proposed for the determination of Ca, Zn and Ce$^{(54)}$ Furthermore, it was applied to PAA$^{(56)}$ and CPAA$^{(57)}$ of Sr in biological materials. In the case of isotope dilution, it is not necessary to determine the chemical yield when the element to be determined is separated before or after irradiation. Hence, Sr was separated chemically before irradiation. Simultaneous determination of Ca, Rb, Sr and Ce was tried in PAA$^{(58)}$ in order to show the applicability of this technique in multiclement analysis.
7 APPLICATION

7.1 Analysis of Light Elements

One of the important features of PAA is the analysis of light elements, such as C, N, O and F. In the book by Engelmann et al., PAA techniques for light element analysis have been described in detail and compared with chemical methods and CPAA. The radioisotopes produced by light elements are positron emitters. In order to analyze such elements, chemical separation after irradiation is mostly necessary. Fedoroff et al. systematically studied the separation of radiocarbon in molten salts and expanded their studies to the simultaneous determination of C and N.

In this section, some analytical examples of carbon and fluorine are described.

7.1.1 Determination of Carbon

Yoshioka et al. determined the carbon impurity in copper and gallium arsenide. In PAA, trace amounts of carbon can be determined by detecting $^{12}$C produced by $^{12}$C($\gamma$,n)$^{11}$C. As $^{11}$C is a positron emitter with a half-life of 20.39 min, a rapid chemical separation of radioactive carbon is necessary after irradiation (yet faster separation schemes have to be applied for oxygen analyses via $^{15}$O; half-life = 2 min). Copper samples were oxidized with Sn as a flux material, and GaAs with Pb$_3$O$_4$. $^{11}$CO$_2$ produced in the combustion process was collected as Ba$_{11}$CO$_3$. The separation procedure was completed within one half-life of $^{11}$C after irradiation. In the case of Cu and GaAs, the sensitivity is 0.02 $\mu$g g$^{-1}$ or 10$^{15}$ atoms cm$^{-3}$, respectively.

Carbon impurity in a highly purified semiconductor has been usually analyzed with IR spectrophotometry. This method uses the relationship between the IR absorbance and the carbon concentration. The absorption of certain wavelengths of IR light is effected by the resonance with a vibration mode of a chemical bond between carbon and the substrate. A nuclear reaction, however, is not influenced by the chemical state of carbon. This fact suggests that the calibration factor between carbon concentration versus absorbance of IR, which had been used formerly, should be reconsidered.

7.1.2 Determination of Fluorine

The ion-selective electrode (ISE) is commonly used for determining fluorine in an aqueous solution. However, trace amounts of fluorine are difficult to detect by an ISE. In PAA, fluorine can be determined by the $^{19}$F($\gamma$,n)$^{18}$F reaction. In the case of high-level sodium contents in the sample, e.g. geological material, the irradiation energy should be reduced to 20 MeV because of the interfering nuclear reaction $^{23}$Na($\gamma$,n)$^{22}$F. For the sensitive analysis of fluorine, pyrolysis and lanthanide precipitation of fluorine-18 after 20 MeV irradiation have been proposed. The detectable concentration level was 0.06 $\mu$g g$^{-1}$ and rocks containing less than 10 $\mu$g g$^{-1}$ of fluorine were analyzed.

7.2 Multielement Analysis of Biological Materials

PAA of biological materials was reviewed by Kuttemperoor and Sato. By the development of high-resolution Ge detectors, PAA has been widely recognized as an efficient multielement determination technique of several biological materials, as reported by Kato et al.

Biological samples, especially several organs of animals and blood, usually contain Na and P at high concentration levels. As the neutron activation cross-section of $^{23}$Na(n,$\gamma$)$^{24}$Na is very large and the Compton scattering by $\gamma$-rays from $^{24}$Na causes very high background in the $\gamma$-ray spectrum, $^{24}$Na often masks other $\gamma$-rays emitted by minor and trace elements in NAA. Furthermore, since $^{32}$P due to phosphorus produces high-energy $\beta$-ray emission followed by bremsstrahlung, detection of trace elements is frequently perturbed, especially in blood and bone samples.

In the case of PAA, high intensity radiation produced in biological samples is due to $^{11}$C, $^{13}$N and $^{15}$O induced by the ($\gamma$,n) reaction from carbon, nitrogen and oxygen, respectively. Fortunately, $\gamma$-ray measurement can be carried out after a comparatively short cooling period, say about 3 h after irradiation, as the longest half-life of the aforementioned nuclides is 20 min ($^{11}$C). Even after 3 h, several short- to medium-lived radioisotopes such as $^{20}$Al from Si, $^{38}$K from K, $^{34}$mCl from Cl, $^{58}$Mn from Fe and $^{87m}$Sr from Sr can often be measured. Moreover, the carbon reaction can be suppressed by activating at an energy below its ($\gamma$,n) threshold (about 20 MeV). Many elements which can hardly be determined by NAA, such as Mg, Ca, Ni, Zn, Sr, Zr, Mo, I and Pb, are easily analyzed by PAA. In 1984, PAA of Zr in biological samples was performed without chemical separation. The radioisotopes of medium half-life, such as $^{24}$Na from Mg and $^{43}$K and $^{47}$Ca from Ca, sometimes show up as a source of undesired Compton background. To remove background activities, Yamashita and Suzuki proposed a group separation scheme using complex formation of metals with tropolone-5-sulfonic acid and collecting on anion-exchange resin.

7.3 Analysis of Geological and Environmental Materials

PAA has been applied for the analysis of geological and environmental materials. About 20 to 30 elements can be determined instrumentally and simultaneously. The list of determinable elements covers major to trace elements which can hardly be determined by NAA, such as Mg, Ca, Ni, Zn, Sr, Zr, Mo, I and Pb, are easily analyzed by PAA. In 1984, PAA of Zr in biological samples was performed without chemical separation. The radioisotopes of medium half-life, such as $^{24}$Na from Mg and $^{43}$K and $^{47}$Ca from Sr, sometimes show up as a source of undesired Compton background. To remove background activities, Yamashita and Suzuki proposed a group separation scheme using complex formation of metals with tropolone-5-sulfonic acid and collecting on anion-exchange resin.
elements, essential to toxic elements, transition metals, heavy metals, alkali and alkaline-earth metals, halogens and others. These elements are Na, Mg, Si, Cl, K, Ca, Sc, Ti, Cr, Mn, Fe, Co, Ni, Zn, As, Rb, Sr, Y, Zr, Nb, Mo, Sb, I, Cs, Ba, Ce, Tl, Pb and U. The pioneering work of multielement analysis of rock and soil was done by Kato et al.,(71,72) and Chattopadhyay and Jervis,(73) respectively. PAA of atmospheric matter was reported by Aras et al. (74) and Kato et al.(75)

Geological and environmental samples contain various elements with high neutron capture cross-section, such as Na, Sc, Mn, Co, Br and Eu. In NAA, these elements induce high intense radioactivity even at trace levels. In PAA, radioactivities induced by major elements such as Na, Mg, Ca, Ti, Mn and Fe are relatively low in most cases. As the (y,p) reactions are the most efficient reactions of Mg, Ca, Ti and Fe, the radioactivities induced by these elements can be reduced by lowering the irradiation energy well below 30 MeV.

Several selected elements advantageously detectable by PAA were also determined. Determination of Ni by a coincidence technique,(76) determination of Nb and Y for the characterization of standard rocks,(77) and determination of I, Ti and U in environmental materials(78) are typical examples. Deep-sea sediment(79,80) and volcanic rocks(81) were analysed by PAA to discuss the sedimentation process and the distribution of minor elements during the formation of rock, respectively.

7.4 Multielement Analysis of Raw Materials and Industrial Products

Gijbels and Hertogen(82) reviewed PAA of ore and minerals. Albert(83) discussed trace analysis using PAA in a review article of nuclear methods. As mentioned before, NAA of certain matrices is sometimes very difficult, because of the self-shielding problem and high radioactivity caused. Typical examples are rare-earth elements, cadmium and boron, which also have large neutron capture cross-sections, and uranium ore and phosphate, which lead to fission products. To verify the capability of PAA in these fields, lanthanides in boron carbide were determined instrumentally by PAA.(84) Detection limits of these elements were found in the submicrogram range. Twenty-eight impurities in boron were also determined by PAA.(85)

8 COMPARISON WITH OTHER ACTIVATION ANALYSIS METHODS

In this section, the different features, advantages and disadvantages of the three activation analysis techniques PAA, CPAA and NAA are compared regarding the irradiation technique, nuclear reactions induced as well as sensitivity and selectivity achievable. Only the basic methods are considered; special techniques like nuclide-induced photodisintegration or 14 MeV NAA are excluded from discussion.

8.1 Irradiation

8.1.1 Photon Activation Analysis

The energy distribution of bremsstrahlung is continuous from zero to the incident electron energy. As high-energy photons have a high penetration power for most materials, a stack of several samples can be irradiated simultaneously. The matrix effect normally is very small in PAA. The energy distribution is not changed drastically during penetration. As the photon flux is decreased exponentially by scattering and absorption in the matter, the photon flux density on each sample should be monitored. Although the incident electron beam is focused, bremsstrahlung cannot be focused. As already touched on, bremsstrahlung has a nonisotropic spatial distribution which depends on the converter thickness and the geometry of the electron beam.

8.1.2 Charged Particle Activation Analysis

As the charged particles are strongly retarded in a sample by scattering, particles are stopped at a certain range. Both the induced radioactivity and the predominant reaction type induced change along with the depth since both flux and energy of the respective particle change. Therefore, range or stopping power of charged particles in each material should be taken into account for the quantitative analysis. It is difficult to irradiate a stack of samples. However, CPAA can efficiently be applied to analyze surface layers of materials. Hence, the surface contamination problem is more imminent than in NAA or PAA. Local heating of the materials by charged particle is a severe problem for the analysis of organic and other sensitive materials. Charged particles can be focused even on extremely small areas. Thus CPAA can be used favorably for the analysis of small spots, e.g. in the study of areal elemental distributions.

8.1.3 Neutron Activation Analysis

Since the neutron has no electrical charge it can penetrate the bulk of samples more easily. The absorption cross-sections of neutrons are strongly dependent on the nuclear properties of each element. The energy distribution of reactor neutrons shows Maxwell–Boltzmann distribution according to the temperature in the reactor. In most cases, many samples can be irradiated simultaneously.
and homogeneously in a capsule. The self-shielding effect of certain elements, such as Cd, should be considered because the neutron flux is locally depressed in the presence of these elements. Neutron beams cannot be focused except, to a certain limited extent, with a neutron beam tube installed at the reactor.

8.2 Comparison of Nuclear Reactions Induced

8.2.1 Photon Activation Analysis

As mentioned above, photonuclear reactions are mainly controlled by the photoabsorption process (giant resonance, see above) giving rise to the \((\gamma,n)\)-type reaction. The resonance energy ranges from about 10 MeV for heavy elements to about 20 MeV for light elements. The yield of the photoneutron reaction increases with atomic number. For analysis, \((\gamma,n)\) and \((\gamma,p)\) reactions are utilized normally. Higher-order reactions such as \((\gamma,\alpha n)\), \((\gamma,np)\) or \((\gamma,T)\) mostly appear as sources of interference. In practice, 30 MeV bremsstrahlung has proven to be optimal in most applications.

8.2.2 Charged Particle Activation Analysis

In CPAA, protons, deuterons, \(\alpha\) and \(^3\text{He}\) particles are commonly used as probes. In the case of charged particle activation, the Coulomb barrier effect should be considered. For heavier elements, higher excitation energies are needed to penetrate the coulomb barrier and to induce nuclear reactions. As several reaction types can be induced at this excitation energy many different radioisotopes are observed and the probability of nuclear interference is considerable. Since the higher atomic number elements are more likely to be subject to nuclear interference than light ones, CPAA is not normally suitable for the analysis of heavy elements.

In the case of deuteron and \(^3\text{He}\) activation, many nuclear reactions are exothermic and can be induced at low excitation energy. Such nuclear reactions have been applied to the analysis of light elements. The irradiation particle and irradiation energy can be selected quasi-freely for the selective analysis of certain elements.

8.2.3 Neutron Activation Analysis

In NAA, thermal and epithermal neutrons are used. Neutrons are absorbed by elements according to the \(1/v\) law and by resonance reactions. The thermal neutron capture cross-section is inversely proportional to the velocity of the neutron, and this is known as "the \(1/v\) law". The resonance reactions induced in the epithermal region are often used for the analysis of specific elements using cadmium shielding of the sample because cadmium has very high absorption cross-section for thermal neutrons. The analysis of light element is very difficult. Unlike in PAA, there is no regularity in the neutron absorption reactions. Nonetheless, NAA can be used for multielement analysis of a large variety of materials.

8.3 Sensitivity and Selectivity of Elements to be Determined and Applicability to Various Kinds of Materials

8.3.1 Photon Activation Analysis

PAA is used for the analysis of light elements such as C, N, O and F, medium elements such as Ti, Ni, Sr, Zr, Nb, and Y, and heavy elements such as Pb, which are very difficult to analyze by NAA. Furthermore, PAA is suitable for the analysis of matrices which contain some elements of high neutron capture cross-section, e.g. boron and noble metals. As photonuclear reaction cross-sections systematically increase with atomic number, PAA can be applied to the analysis of heavier elements in light matrices, such as natural materials (rocks, soils, dusts, organics, etc.). The sensitivity for trace analyses is mostly sufficient (microgram per gram region and below), although not as good as in NAA for the average case. Using appropriate equipment and with the exception of a few interference cases (see above), PAA is highly selective due to discrete energy signals of the respective activation products.

8.3.2 Charged Particle Activation Analysis

CPAA is advantageous particularly for light element analysis. CPAA has often been applied to the impurity analysis of industrial materials. The shape of the sample is critical, so the application is somewhat restricted. The average sensitivity is comparable to that of PAA whilst the selectivity is frequently limited due to numerous nuclear reactions eventually induced in the individual element.

8.3.3 Neutron Activation Analysis

NAA can detect many elements instrumentally, except for light elements. Extremely low detection limits are achievable for a good number of elements, e.g. several rare earth elements, noble metals and others; the respective detection limits are lower partly by orders of magnitude, as compared with PAA and CPAA. Thus, NAA is suitable for sensitive analysis of trace elements in various types of materials. However, interference through eventual excessive matrix activities have to be taken into account. Moreover, in the normal case, only small sample masses should be irradiated because of the intense radioactivity induced. Thus, problems of representativeness might arise. As to the selectivity, see section 8.3.1.
9 CONCLUSION

PAA offers sufficient sensitivity for the analysis of a great number of elements covering the entire periodic table. A large variety of sample types can be analyzed. The quality of PAA results can be improved by application of quantitative methods, such as the internal standard method or the stable isotope dilution method. In the case of the classical comparative method, the use of synthetic multielement standards of acrylamide or silica matrix yields significant improvement of accuracy.

In PAA (also in NAA), samples can be measured repeatedly. A laboratory automation system using a small robot for sample changing\(^{86,87}\) has released analysts from the tedious work of sample handling and data acquisition during \(\gamma\)-ray measurement. Moreover, many “human” sources of error can be avoided. Such systems also assist researchers of many other fields using activation analysis and other radioactivity measurements.

Although other, nonactive analytical methods underwent dramatic improvement in recent years concerning sensitivity and other features, PAA and other activation techniques can offer specific advantages, e.g. the analysis of elements difficult to analyse by other methods. Moreover, purely instrumental and even nondestructive analyses are state-of-the-art in PAA.

Thus, as trace characterization is still important in material science, environmental science and other fields, PAA can contribute to the analysis of light to heavy elements.

Particle-induced X-ray emission (PIXE) is the most popular among the ion beam analysis (IBA) techniques, which are based on the use of the specimen to be analyzed as a target for a beam of accelerated particles. The detection of the radiation induced by the beam bombardment is then used to discriminate and quantify the presence of the different elements in the specimen. In PIXE, what is exploited is in particular the X-rays emitted from the target, whose energies are characteristic of the emitting atomic species. After a general, simple description of the main features of PIXE, with a short historical overview and a brief comparison to other X-ray fluorescence (XRF) techniques, the article covers in greater depth all the specific aspects of this “nuclear” technique. The basic aspects of X-ray emission from the atoms are first recalled; then, the extraction of quantitative compositional data from thin and thick specimens is explained, and a discussion is given of the excellent performance of PIXE in terms of minimum detection limits (MDLs), and of the factors affecting them. A technical description then follows of how proper beams for PIXE are produced and of the experimental set-ups commonly used, with particular emphasis on the external-beam arrangements. The X-ray detector characteristics, the electronics for constructing the energy spectra, and the software processes for their deconvolution, leading to the extraction of quantitative data, are then briefly described. The last section surveys the main analytical applications of PIXE in various fields (environmental monitoring, biomedicine, earth sciences, cultural heritage), with no intent of exhaustiveness but rather with the purpose of focusing on when and why PIXE may be particularly suitable in each of them.

1 INTRODUCTION

1.1 General Features

PIXE is a technique for the elemental analysis of a sample. This is used as a target for the bombardment with a beam of accelerated particles; the interactions of the beam particles with the target atoms lead to the emission of X-rays of characteristic energies, through the detection of which the target composition can be deduced. The PIXE technique is often also referred to as proton-induced X-ray emission, owing to the fact that in this technique protons are almost universally chosen to induce X-ray emission. For this reason, the following discussion always considers the case of protons; no difference of either theoretical or practical relevance occurs anyway with beams of other particles. The PIXE technique belongs to the category of IBA techniques, and is perhaps the most widely used among them.

The method makes it possible to detect simultaneously and with great sensitivity almost the full range of elements present in the analyzed sample. In practice, some limitations partially restrict the number of detectable elements, but the multi-element capability is actually retained to a very large extent. As a rule of thumb (to be better specified below), one might state that in a single measurement – typically lasting few minutes – all elements with $Z > 10$ are detected with MDLs down to trace levels.
The working principle of PIXE is quite simple. Using a small (usually electrostatic) accelerator, a beam of particles is produced with an energy of typically 2–3 MeV. The beam particles, when impinging on a target, interact with atoms and nuclei of the target itself: in particular, the inner shells of the target atoms may be ionized. The inner shell vacancy is promptly filled (within a time interval of the order of $10^{-15}$ s) by an outer electron, and the difference $\Delta E = E_o - E_i$ of the electron binding energies $E_o$ and $E_i$ in the outer and inner shell is released. One of the processes through which the energy $\Delta E$ can be released is just the emission of an X-ray of that energy. A competing mechanism (the Auger effect) is the energy transfer to another electron of an outer shell, which is consequently ejected with a kinetic energy $E_k = \Delta E - E_i$, where $E_i$ is the binding energy of the electron to which $\Delta E$ is transferred. Figure 1 shows schematically the processes of X-ray and Auger electron emission.

The energy of the emitted X-ray (or Auger electron) is clearly characteristic of the emitting atomic species, being the difference of electron binding energies that are indeed characteristic of the atomic species. Thus, the energy spectroscopy of the X-rays from the sample during particle beam bombardment provides an analysis of its composition. Such an analysis is multi-elemental, because all the atomic species present in the target undergo interactions with the beam particles, and therefore emit characteristic X-rays. It is also quantitative, because during an irradiation the number of interactions of the beam particles with the atoms of a given species is obviously proportional to the abundance of atoms of that species in the target. Under most circumstances (better specified in the following) the analysis is also totally nondestructive, because the beam particle–target atom interactions do not produce significant alterations in the target and involve only a tiny fraction of the target atoms. In any case, the possibility of further analysis (by the same or different techniques) is guaranteed for the same specimen.

The principle of operation of PIXE is the same as that exploited to perform elemental analysis through electron probe microanalysis (EPMA) or XRF, but with a different ionizing agent (protons rather than electrons or primary electromagnetic radiation, respectively). This difference has consequences in terms of important analytical parameters such as MDLs, range of detected elements, or sample depth probed (as briefly discussed later).

The possibility of performing PIXE while keeping the sample in the atmosphere (nonvacuum or external PIXE), and that of miniaturizing the beam size down to 1 µm or even less (micro-PIXE), make it a very versatile technique. All kinds of samples may be quantitatively analyzed: solid, gaseous, or liquid (the latter two with an external beam). Elemental mapping may also be performed by scanning the beam on the sample during analysis (or moving the sample under the beam).

In PIXE, the detection and discrimination of X-rays emitted under beam bombardment is usually performed through the use of solid state Si(Li) detectors (or, much less frequently, hyperpure Ge detectors), which discriminate the different X-rays by their different energies. The detector response signals are proportional to the energy releases within the active volume of the detector; this way of discriminating different X-rays is therefore called energy-dispersive spectroscopy (EDS). The energy resolution is generally adequate for unambiguous discrimination. Conventionally, resolution is given as the full width at half-maximum (fwhm) of the peak corresponding to the 5.9-keV X-ray from Mn. A typical value is around 160 eV, but even better resolution may be reached, especially for small-surface detectors and when a long time constant is used for the linear shaping of the detector signals. To give an idea of the kind of information collected, Figure 2 shows two typical X-ray spectra obtained with Si(Li) detectors in a PIXE measurement of a sample of aerosol. We return later to a discussion of the characteristics of the spectra (in particular the background shape) and to the way of treating partially overlapping lines. Here the intention is to point out that the multi-element analytical capability is a real feature of PIXE with EDS, and not just a theoretical claim.

![Diagram of an inner shell ionization induced by proton bombardment, followed by Auger electron or X-ray emission (alternative to each other). (Reproduced by permission from Johansson et al.)](image)
Figure 2 PIXE spectra from a sample of aerosol collected on a Millipore filter. The spectra refer to the same sample, but have been recorded simultaneously by two Si(Li) detectors in different geometries (see Figure 11, and the discussion of two-detector set-ups in section 2.6.3). The spectrum acquisition time was about 7 min, at a proton beam current of 5 nA.

By using Bragg spectrometers that exploit X-ray diffraction from a crystal, wavelength-dispersive spectroscopy (WDS) may also be performed, which allows a much better energy resolution (by a factor of 50 or so). The WDS technique is clearly at a premium to solve close multiplets of X-rays of similar energies from different elements, but a serious drawback is a drastic drop of detection efficiency. In typical PIXE set-ups for analytical purposes, WDS is therefore never accomplished, because one of the great analytical pros of the technique, i.e. its high sensitivity, would be lost. After all, even with EDS most ambiguities may be solved by using other X-rays from the same element as markers of its presence. Thus, the use of WDS is left in general to studies of basic atomic physics, such as changes of electron binding energies as a function of chemical state, rather than to analytical applications. For this reason, we will not discuss WDS any further in this context.

1.2 Brief Historical Overview and Review Literature

The PIXE technique was established as a universal analytical technique by Johansson et al. in the early 1970s. Its popularity and the range of applications have constantly increased over the years. Today (1999), tens of laboratories throughout the world currently use PIXE for elemental analysis in fields as diverse as environmental pollution, biology and medicine, earth sciences, material sciences, art and archaeology, historical document examination, and forensic science. Comprehensive descriptions of the theoretical basis of the technique and its practical use in the main fields of application are available.\(^1,2\)

Dedicated conferences on “Particle-induced X-ray Emission and its Analytical Applications” have been held every third year since 1977; PIXE sections have been and are present in many other, more general, series conferences (e.g. International Conference on Ion Beam Analysis, European Conference on Accelerators Applied to Research and Technology, and others). Specific conferences on nuclear microprobes (where micro-PIXE applications are widely represented), and more recently on the applications in the field of biomedicine (bio-PIXE Symposia), are also periodically held.

The literature on PIXE work is distributed over several journals dealing with the fields of the specific applications. However, the above-mentioned Proceedings of the International PIXE Conferences – published by North Holland as separate issues of the review Nuclear Instruments & Methods in Physics Research, Section B – are a good source of concentrated information concerning both applications and basic physical and technological advancements. The journal *International Journal of PIXE* (published by World Scientific Publishing Co Pte Ltd, Singapore) contains topical and review articles on the various fields of application.

1.3 Comparison with other X-ray-based Analytical Techniques

1.3.1 Electron Probe Microanalysis

1.3.1.1 Minimum Detection Limits

The absence of a primary bremsstrahlung (BS) continuum in the PIXE spectra (section 2.3.1), with the consequent low background in the energy spectra, is the main reason for much better (i.e. lower) detection limits in PIXE with respect to EPMA. In the latter, primary BS gives rise to a considerable, continuous background that extends to 20–30 keV (20–30 kV being the typical accelerating voltage used in the electron gun). This background is therefore present over all the energy region of interest for elemental analysis by X-ray line spectra. As X-ray production cross-sections for EPMA and PIXE are comparable under optimum conditions, the much lower backgrounds in PIXE spectra translate into better MDLs, typically lower by more than two orders of magnitude in PIXE with respect to EPMA.

1.3.1.2 Probed Depth

The range of electrons typically used in EPMA \((E_e = 20–30\text{ keV})\) is of the order
of a few micrometers at most, in light-\(Z\) matrices. This is consequently also the investigated depth from surface with EPMA, for all elements. As discussed below, in typical PIXE (\(E_p = 2 – 3\) MeV), the range traversed by protons is about 10 times larger; for higher-\(Z\) elements (detected through higher-energy X-rays) the probed depth is consequently much larger in PIXE than for EPMA. For the detection of lighter elements the effects of X-ray self-absorption (section 2.2) become dominant after only a few micrometers and the difference in the probed depth between the two techniques becomes smaller.

1.3.1.3 Space Lateral Resolution With an electron beam it is relatively standard to obtain beam spots on the target of less than 1 \(\mu\)m. Elemental mapping by scanning electron microscopy (SEM) is therefore easily performed at an EPMA facility. Standard PIXE is performed with larger beam cross-sections, but the possibility of micro-PIXE down to beam sizes below one micrometer exists, as briefly described in section 2.7. This makes it possible to perform trace-element two-dimensional mapping of a sample. However, it should be pointed out that EPMA yields excellent space resolution as a standard feature, whereas micro-PIXE requires sophisticated tuning and cannot therefore be considered a routine analytical technique.

1.3.1.4 Possibility of Nonvacuum Analysis With EPMA, it is mandatory to analyze the sample in vacuum. When large objects are investigated, this implies taking a sample of the material, which may be problematic when analyzing precious items. With PIXE, external beams are easily used (most practical aspects of the experiment get easier) which makes the analysis of large objects feasible with no need to take samples and no damage at all.

1.3.2 X-ray Fluorescence

1.3.2.1 Minimum Detection Limits Both PIXE and XRF can be used for trace-element analysis down to parts per million (ppm) levels. The difference between the two is the behavior of the sensitivity curve with \(Z\). Generally speaking, due to the different ionization mechanisms (and the consequent trends of X-ray production cross-sections) XRF has lower MDLs for higher-\(Z\) elements than PIXE, whereas the analytical capability of PIXE extends to lower-\(Z\) elements. However, for both techniques the sensitivity curve can be varied by changing the energy of the ionizing agent (primary electromagnetic radiation and protons, respectively). The XRF method may become totally blind to higher-\(Z\) elements when choosing an exciting radiation suitable for obtaining lower MDLs for lower-\(Z\) elements, and vice-versa, whereas PIXE preserves the total range of detected elements even when optimized (by varying the proton energy) with a better sensitivity to lighter or heavier elements.

1.3.2.2 Probed Depth XRF probes considerably greater depths than standard energy PIXE as far as the heavier elements are concerned. For the lighter-\(Z\) elements (under conditions when XRF can detect them) it is again the self-absorption of low-energy X-rays – rather than the excitation mechanism – that determines the effective probed depth. Thus the difference is smaller.

1.3.2.3 Lateral Resolution The possibility of obtaining real microbeams for PIXE has been mentioned in section 1.3.1. As far as XRF is concerned, until recently the typical spot over which XRF analysis was carried was of the order of square centimeters. The analysis of much smaller spots required strong collimation, and this drastically decreased the exciting radiation intensity and therefore made measurement times unduly long. However, the recent development of focusing techniques for X-radiation (based on capillary light-guides suitable in the range of X-ray wavelengths) has opened up new possibilities of miniaturizing the exciting X-ray beams for XRF, while still preserving acceptable intensities. The useful spot size obtained with these techniques is now of the order of some tenths of a square millimeter.

1.3.2.4 Nonvacuum Analysis As with PIXE, XRF can be easily accomplished in nonvacuum conditions (although commercial XRF equipment is usually designed for in-vacuum analysis). In this respect there is no technical difference between the two techniques.

1.3.2.5 Nonlaboratory Analysis Portable XRF equipment has been developed, mostly based on the use of an X-ray tube as the source of electromagnetic exciting radiation. Although some limitations exist when performing fully quantitative analyses – especially for light elements – the opportunity to perform in situ analyses on non-transportable materials is considerable. The need for a particle accelerator to produce the beam that excites X-ray emission makes conventional PIXE an intrinsically nonportable technique. However, in the late 1990s portable PIXE equipment, based on the use of a purely \(a\)-emitting source (\(^{210}\)Po), has been developed and tested with success\(^{3,4}\). The present limitation of this apparatus is the low intensity of the \(a\)-beam due to isotropic emission of the particles from the source. This makes the measurements much more time-consuming than in the laboratory. Further developments in the relative source–sample–detector geometry are underway to improve the performance of this interesting variant to standard PIXE.
2 IN-DEPTH REVIEW OF THE TECHNIQUE

2.1 Basic Aspects of X-ray Emission from Atomic Shells

Let us first recall the spectroscopic nomenclature for atomic shells and for X-rays corresponding to electron transitions between them.

The potential energy is set to zero for free electrons, whereas electrons in the atomic shells have increasingly negative energies the more bound they are. The innermost electronic shell (principal quantum number \( n = 1 \)) is the K shell, and corresponds to the most tightly bound electrons; therefore, for any given element, K electrons have the minimum energy value. Examples of K-level energies are \(-1072\) eV for Na, \(-4038\) eV for Ca, \(-7113\) eV for Fe, \(-11103\) eV for Ge, \(-25514\) eV for Ag, \(-37441\) eV for Ba, and \(-88005\) eV for Pb.

The second shell (principal quantum number \( n = 2 \)) is the L shell, with subshells L1, L2 and L3 corresponding to \((l = 0, \ j = 1/2)\), \((l = 1, \ j = 1/2)\), \((l = 1, \ j = 3/2)\), respectively. Examples of level L1, L2, and L3 energies are: \(-63.3\), \(-31.1\), and \(-31.0\) eV for Na; \(-438, -350, and -346\) eV for Ca; \(-846, -721, and -708\) eV for Fe; \(-1414, -1248, and -1217\) eV for Ge; \(-3806, -3524, and -3351\) eV for Ag; \(-5988, -5624, and -5247\) eV for Ba; and \(-15860, -15200, and -13035\) eV for Pb.

The sequence of other shells is then M, N, and O, with principal quantum numbers \( n = 3, 4, \) and 5, respectively, with less tightly bound electrons (this applies to higher-\( Z \) elements having a large number of electrons).

Once a vacancy is created in an inner shell (by any ionizing agent), not all electronic transitions from outer shells or subshells are possible. Transition selection rules arise from quantum mechanical laws, so that only certain transitions are permitted, each having a well defined probability.

In the case of ionization from the L or superior shells, the Coster–Kronig effect must be taken into account. For the L shell, this consists of a nonradiative transfer of a vacancy, primarily created in the L1 or L2 subshell, to a higher L subshell (L2 or L3 for primary L1 ionization, L3 for primary L2 ionization). Coster–Kronig transitions occur before the filling from an outer electron takes place; the electron transition energy is then varied. The probabilities of L1 to L2 (\( f_{12} \)), L1 to L3 (\( f_{13} \)) and L2 to L3 (\( f_{23} \)) Coster–Kronig transitions are high (up to over 50\% for the L1 to L3 transition), and vary with atomic number. Similar and even more complicated effects take place when the primary ionization occurs in a shell higher than L. Although the Coster–Kronig effect is important from the point of view of basic atomic physics, it has no practical consequence for quantitative analyses based on induced X-ray classification, such as PIXE, EPMA, and XRF. In fact, it can be treated as an effective change of ionization probability of the various subshells and automatically taken into account when performing quantitative PIXE measurements, for which the knowledge of ionization cross-sections is essential (section 2.2).

Once an ionization has been produced in an inner shell, deexcitation of the atom can be accomplished by X-ray or Auger electron emission. The ratio of the number of X-ray emissions to the total number of ionizations produced in the given shell is called the fluorescence yield relative to that shell and is usually indicated with \( w \) (\( w_K, w_L, \) etc.). For the L and higher shells, subshell ionizations and consequently subshell fluorescence yields can be considered separately.

Fluorescence yields may be calculated theoretically and measured experimentally.\(^{5-8}\) They are a function of the atomic number \( Z \) and Figure 3 shows the behavior of \( w_K \) and \( w_L \) versus \( Z \).

The nomenclature for X-rays emitted as a consequence of an outer-electron transition following inner-shell ionizations recalls both the primary vacancy location and the filling electron provenance. These are referred to as K-series, L-series, M-series, etc. X-rays, depending on the initially ionized shell. Within each series, the further specification is then related to the provenance shell of the electron. \( K_a \) and \( K_{\beta_1} \) X-rays correspond to the filling electron coming from the L and superior shells, respectively, with still further distinctions (\( K_{a_1}, K_{a_2}, K_{\beta_1}, K_{\beta_2}, K_{\beta_3} \)) depending on the provenance subshells. Figure 4 gives a summary of the X-ray nomenclature for the main lines of the K and L series.

Because electron binding energies increase with \( Z \), X-ray energies also increase with the atomic number. Figure 5 shows the trend for X-ray energies of the K and L main lines as a function of \( Z \).

Within each X-ray series, the intensity ratio of the different transitions varies with \( Z \).

**2.2 Quantitative PIXE Analysis**

Although a unified mathematical treatment of the procedure for a quantitative PIXE analysis might be given for all kinds of samples, it is easier to understand the principle by first examining the case of thin samples.

An operational definition of “thin” and “thick” for a PIXE measurement is given below; for the moment, when referring to a thin specimen let us think of a few atomic layers.

### 2.2.1 Thin Specimens

The proton interactions with the inner shell electrons of the target atoms produce ionizations. The number of ionizations $N_{\text{ion},j}(Z)$ produced in a given shell $j$ ($j = K,L,M,\ldots$) for a given atomic species $Z$ in the target is obviously proportional to the target concentration of that atomic species, to the number of particles $N_p$ having passed through the target and to the thickness $t$ of the sample (Equation 1):

$$N_{\text{ion},j}(Z) = \sigma_{\text{ion},j} N_Z t N_p$$  \hspace{1cm} (1)

where $N_Z$ is the number of atoms of atomic number $Z$ per unit volume. The term $\sigma_{\text{ion},j}$ is the ionization cross-section for the given shell $j$. As seen from Equation (1), it has the physical dimensions of an area, and is clearly a measure of the probability of the interaction giving rise to the specific ionization. Except for the case of the K shell, ionization cross-sections are made up of more terms, corresponding to ionizations of the various subshells, for instance $\sigma_{L_1}$, $\sigma_{L_2}$, and $\sigma_{L_3}$.

Measured values of K- and L- ionization cross-sections have been reported in a large number of papers; a much smaller amount of data is available for the M-shell case. For the K shell, a collection of measured values is available and a set of reference values based on statistical analysis of a compendium of published data has been compiled. With the exception of very low atomic numbers, the results of the so-called ECPSSR theory (developed from the pioneering work of Brandt and Lapicki), treats the deflection and velocity change of the particles due to the Coulomb (C) field, the perturbation of the atomic stationary state (PSS) by the projectile, relativistic effects (R), and energy loss (E) during the collisions between beam particles and atomic electrons. For each element, the cross-section data (reference or theoretical) may be fitted with a fifth-order logarithmic polynomial. A universal treatment over a wide range of elements and proton energies with just six fitted parameters altogether, yielded – in the early stages of development of PIXE – a reasonable although not completely satisfactory reproduction of the tabulated data. However, using a distinct set of polynomial coefficients for each atomic number, tabulations can be reproduced within 1%.

The quantification of the high-energy contribution of the M-series X-rays was done. However, although little use is normally made of the M-subshell ionization cross-sections, and consequently the agreement less satisfactory.

The trend of $\sigma_{\text{ion,K}}$ and $\sigma_{\text{ion,L}}$ with proton bombarding energy, taken from ECPSSR calculations for some elements, is shown in Figure 6. A strong decrease with increasing $Z$ is apparent, especially for the K-shell ionization cross-sections. A strongly increasing trend with increasing $E_p$ occurs within the range of proton bombarding energies usually adopted. The cross-section reaches a maximum when the projectile velocity matches that of the ejected electron. Further increase of projectile energy results in a slow decrease in cross-section. It is apparent from Figure 6 that the increase with $E_p$ is larger for higher values of $Z$ so that, in general, working at higher energies makes the analysis of heavier elements comparatively more sensitive.

For the M shell, much less systematic work has been done. However, although little use is normally made in PIXE of the detected M-series X-rays for the quantification of the high-Z elements, knowledge of M-subshell ionization cross-sections, and consequently of the intensity ratios of M lines, would be important.

Indeed, in X-ray spectra from complex samples, the M lines from high-Z elements overlap the K or L lines of lighter elements so that a safe deconvolution of the multiplets must rely also on (experimental or theoretical) knowledge of the intensity ratios of the various M lines.

The product of ionization cross-section and fluorescence yield for a given shell gives the cross-section $\sigma_X$ for the production of an X-ray of the corresponding series; from what has been said it follows that $\sigma_X$ is also a function of $Z$ and $E_p$. As stated above, within each series the branching ratio among the different lines is a slowly varying function of $Z$ and, for the L shell, this also depends on the particle bombarding energy.

In terms of X-rays produced, the equivalent of Equation (1) is given by Equation (2):

$$N_X(Z) = \sigma_X N_{Zt} N_p$$  (2)

The angular distribution in the emission of the produced X-rays is isotropic with respect to the beam incidence.

Equation (2) can be rewritten in terms of areal density $\rho Z t$ of the element $Z$ (mass per unit area normal to the beam, with $\rho Z$ standard volumic mass density) as:

$$N_X(Z) = \sigma_X \frac{N_{Av} \rho Z t Q}{A}$$  (3)

where $N_{Av}$ is Avogadro’s number and $A$ the atomic mass of the species. In Equation (3), the number of protons $N_p$ passing through the target is more conveniently expressed by integrated beam charge $Q$ divided by unit charge $e$ of the particles. Indeed, $Q$ is usually a measurable quantity (see section 2.4.3).

The capability of performing a fully quantitative analysis with PIXE in essence derives from Equation (3).

In a thin target, for any given element the X-ray production cross-sections are constant throughout the target (because the beam energy loss is negligible, i.e. all interactions happen at the same proton energy, say $E_0$), and the number of detected X-rays is a well-defined fraction of those produced (isotropic emission of all X-rays). From Equation (3), one obtains the number $Y_0$ of X-rays from the element $Z$, detected during a measurement, simply by taking the overall detection efficiency into account. The latter is the product of a geometrical factor (related to the solid angle $\Omega$ covered by the detector) and of an intrinsic efficiency $\varepsilon_{\text{det}}$, a function of the X-ray energy (and therefore of $Z$) depending on the detector characteristics (section 2.6.1):

$$Y_{0X}(Z) = \sigma_X (Z, E_0) \frac{\Omega}{4\pi} \varepsilon_{\text{det}} \frac{N_{Av} \rho Z t Q}{A}$$  (4)
Equation (4) can be reorganized as follows (Equation 5):

\[ Y_{0X}(Z) = \left( \sigma_{X}(Z, E_0) \frac{\Omega}{4\pi} \epsilon_{\text{det}} \frac{N_{Av}}{Ae} \right) Q_{\rho Zt} \]  

or (Equation 6):

\[ Y_{0X}(Z) = \eta Q_{\rho Zt} \]

by defining an efficiency factor \( \eta \) for the given X-ray, beam energy, detector and geometry (Equation 7):

\[ \eta = \eta(Z) = \sigma_{X}(Z, E_0) \frac{\Omega}{4\pi} \epsilon_{\text{det}} \frac{N_{Av}}{Ae} \]

From Equation (6) it is easily seen that – provided \( \eta \) is known – the areal density \( \rho_{Zt} \) for a given element can be obtained by measuring the corresponding X-ray yield on the detector and the integrated beam charge on the target. Knowledge of \( \eta \) is in principle possible even in absolute terms, because the physical factors in Equation (7) are either known (\( \sigma \), see above) or measurable (\( \Omega, \epsilon_{\text{det}} \), see section 2.6). In practice, rather than relying on the absolute knowledge of the terms in Equation (7) for determining the efficiency factors \( \eta(Z) \), the latter are obtained experimentally through Equation (5) itself. This is performed by bombarding a series of thin standards containing known quantities \( \rho_{Zt} \) of the various elements, and measuring the corresponding X-ray yields and the integrated beam charge. The measurements on the standards must be performed using exactly the same geometry, with the same absorption layers (if any) and at the same beam energy as on the samples. The analytical procedure for the determination of elemental concentrations in unknown thin samples is therefore a relative procedure.

Figures 7 and 8 show the curves for the efficiency factor as a function of X-ray energy (i.e. \( Z \)), for the K and L series, respectively, in a typical detector geometry. As a result of the very large variation of X-ray production cross-section over \( Z \), the efficiency factor in a given geometry also spans a wide range of values, drastically decreasing for the detection of X-rays of higher-\( Z \) elements within the same series. In addition, the intrinsic efficiency of Si(Li) detectors progressively drops at X-ray energies above 20–25 keV, which corresponds to K-series X-rays of elements around \( Z = 50 \). This would create a loss of sensitivity to the detection of heavier elements; the problem is to a large extent overcome by the fact that L-series X-rays (produced with much larger cross-sections, see Figure 6) can be used as markers of their presence. At these values of \( Z \) the L-series X-rays are well within the useful range for an Si(Li) detector (see section 2.6.1), and this holds true for L-series X-rays up to the highest \( Z \) values. It will also be seen that in the higher-energy region of the spectrum the background is much lower, thus improving detection of weak lines. Further expedients to make detection limits more homogeneous through the widest possible range of \( Z \) are discussed in section 2.6.3.

2.2.2 Nonthin Specimens

Before seeing how quantitative analysis may be performed in the general case, it is useful to consider more carefully what “thin” and “nonthin” mean for PIXE analysis. The two physical effects that concur to determine whether a specimen is nonthin as far as PIXE analysis is concerned are:

- the beam energy loss while penetrating the sample;
- the self-absorption of X-rays produced in the interior of the sample.
A sample is thin if one may neglect these effects (the so-called matrix effects) and assume therefore:

- that all interactions happen at the same beam energy;
- that X-rays produced by the beam inside the target, emitted within the acceptance solid angle of the detector, have negligible probability of being lost to detection due to interactions inside the sample material itself.

By the expression “thin sample”, we mean that the quantitative results obtained from its PIXE analysis by neglecting matrix effects are correct. Of course, this is never absolutely true and the validity of the thin-target approximation depends on the degree of accuracy one is looking for. Another important fact to bear in mind is that the thickness below which a sample may be considered thin depends both on its composition and on the X-ray energy that is observed (i.e. on the element, the abundance of which one is quantifying). Indeed, both beam stopping power and X-ray attenuation due to self-absorption depend on the average $Z$ of the material; X-ray attenuation also strongly depends on the X-ray energy, increasing dramatically with decreasing X-ray energy. As a result of the latter point, a given physical thickness may be still considered “thin” as far as detection of a lower-energy X-ray from a lighter element. Approximately below 10–20 $\mu$g cm$^{-2}$ a sample of a medium-$Z$ matrix can be assumed to be thin (to about 1% or better) for the quantification of all elements usually detected in PIXE (X-ray energies above 1 keV, corresponding to Na K$_\alpha$). For the detection of higher-$Z$ elements, detected through X-rays in the energy range above 6–7 keV, even a thickness of 2–300 $\mu$g cm$^{-2}$ might be considered thin.

When the sample thickness is such that the consequences of beam energy loss and X-ray absorption cannot be neglected, the extraction of quantitative information from the X-ray intensities in PIXE spectra is more complicated, but can still be dealt with. Indeed, both the physics of beam particle–target atom collisions, producing the energy loss, and that of X-ray interactions, producing the self-absorption effect, are well known and can be properly taken into account. The X-ray yield is obtained by integration of the contributions from the different depths inside the target. For each of them, one has to consider the proper X-ray production cross-section (which is a function of $E_p$ and therefore of the depth from surface) and the reduction in the detected X-ray intensity, which also depends on the depth at which they are produced, because those X-rays produced deeper in the sample are more affected by self-absorption.

The detected X-ray yield for a given element is obtained by the following generalization of Equation (4):

$$Y_{X_j}(Z) = \frac{\Omega}{4\pi} \frac{Q}{e} \frac{N_{X_j}}{A} \rho Z T_0 \sigma_X(Z, E_p)e^{-\mu(E_p)\cos\theta} dx$$

In Equation (8) $T$ is the finite thickness of the sample and the exponential term accounts for the self-absorption of X-rays produced at a general depth $x$ from the surface. The X-ray intensity attenuation coefficient $\mu$ is a function of the matrix composition and of the X-ray energy. The usual detection geometry (Figure 9) has been assumed in Equation (8), where $\theta$ is the angle at which the detector is placed with respect to the target normal.

In Equation (8), one should consider that $x$ and $E_p$ can each be expressed as a function of the other through the beam mass stopping power $S = dE_p/\rho dx$ (a function of the matrix composition and of $E_p$). Equation (8) can therefore be expressed as Equation (9),

$$Y_{X_j}(Z) = \frac{\Omega}{4\pi} \frac{Q}{e} \frac{N_{X_j}}{A} \rho Z E_0 - \Delta E \sigma_X(Z, E_p)$$

$$\times e^{-\mu(E_p)\cos\theta} \frac{dE_p}{S(E_p)}$$

where $E_0$ is the initial beam energy (at target entrance) and $\Delta E$ is the total beam energy loss through the target thickness $T$ (Equation 10):

$$\Delta E = \int_0^T S dx$$

In general, for any X-ray, a matrix correction factor $F_{X_j}$ is introduced, defined as the ratio between the ideal yield $Y_0$ that would be obtained from the same target, in the absence of matrix effects, and the actual yield $Y$.
(Equation 11):

\[ F_X(Z) = \frac{Y_{0X}(Z)}{Y_X(Z)} \quad (11)\]

Therefore, from Equations (4) and (8), one obtains

\[ F_X(Z) = \frac{T \sigma_X(Z, E_0)}{\int_{0}^{T} \sigma_X(Z, E_p(x)) e^{-\mu X \cos \theta} dx} \quad (12)\]

By recalling Equation (6) for \( Y_0 \), Equation (11) implies (Equation 13):

\[ \rho [Z] = \frac{Y_X(Z)}{Q h_Z E_0} F_X(Z) \quad (13)\]

where \( \eta \) is the efficiency factor, resulting from the measurements on thin standards at the surface beam energy \( E_0 \). In principle, therefore, the quantitative analysis of nonthin samples can be obtained from the detected yields \( Y_X(Z) \), by considering the samples as thin (use of thin target efficiency factors) and then applying the proper correction factors \( F \) to account for matrix effects.

The problem remains as to how to obtain proper correction factors. This is a priori a problem, but can be solved quite well in many cases, such as when analyzing a homogeneous target of known thickness. The equivalent to the exact knowledge of target thickness \( T \) is a much more frequent case than might be thought at first sight. In fact, whenever the thickness, although unknown, is larger than the proton range \( R_p \) (of the order of 50–100 \( \mu \)g cm\(^{-2} \)), for the calculation of \( F \) it can be replaced by \( R_p \) itself, or by any larger value. In this case one talks about “infinitely thick” targets, where of course this term only implies that \( T > R_p \). Even before this limit is reached, at least for the lower-\( Z \) elements, the exponential term in Equations (8) and (12) may be so small after a certain depth that the expression under the integral goes to zero and contributions from deeper layers can be neglected. In simple terms, for the lower-\( Z \) elements the dominant matrix effect is self-absorption rather than the decrease in production cross-section due to the beam stopping down; their X-rays continue to be produced at depths from which they will not reach the detector due to the self-absorption effect. Actually, as far as the detection of lower-\( Z \) elements is concerned, the target becomes infinite much before the condition \( T > R_p \) is fulfilled.

It is also necessary to make an assumption about the matrix composition to evaluate the integral in Equation (12), because both \( \mu \) and \( S \) are matrix dependent. If this composition is not known, as is usually the case in analytical work, the adopted technique then becomes an iterative procedure. The zeroth-order approximation of the matrix composition is obtained by neglecting all the matrix effects, i.e., by using Equation (13), with \( F(Z) = 1 \) for all values of \( Z \). The matrix composition obtained by the areal densities thus deduced for the detected elements is then used to compute the stopping power and absorption coefficients to be used in Equation (12). From that, a first-order approximation of the matrix composition is obtained by reworking Equation (13), and this composition is then used again to compute the stopping power and absorption coefficients to be used in Equation (12), and so on iteratively. The procedure rapidly converges and a good estimate of the actual composition can be given. Two aspects must be pointed out in this respect.

First, the assumption is made of a homogeneous composition as a function of depth through the explored depth range (recall that we are talking about tens of micrometers at most). However, this assumption may be completely wrong, and the only way to check its validity is to perform further independent analyses with other techniques (or even simultaneously with other IBA techniques, or performing subsequent PIXE runs at different proton bombarding energies).

Second, the various approximations of the matrix composition, if based on just the PIXE-detected elements, can be largely defective because very light elements are hidden from the analysis (typically, this happens for \( Z < 11 \), but the actual limit depends on the specific set-up). The undetected fraction can be important and affects the actual matrix effects, which depend on all the elements present in the material. In many practically important circumstances the undetected fraction may be known independently, on the basis of separate measurements such as simultaneous measurements with other IBA techniques. In other cases, it can be indirectly deduced by the concentrations of the detected fraction itself; this is the case for instance in the analysis of rocks of volcanic origin. Here all elements can be considered to be present in the form of oxides, so that each element bears an amount of oxygen in a well-defined proportion to the detected element’s abundance. Under these circumstances, the undetected fraction is well estimated and a good approximation of the whole matrix composition can be used to compute the factors \( F \) from Equation (12). Finally, it should be remembered that both the stopping power and the absorption coefficients depend on the matrix composition, but not so dramatically as to alter significantly the final values obtained by the iterative procedure of Equation (12) if a minor change in the matrix composition assumption is made. Obviously, this affects the different elements in a different manner: as a rule of thumb, lighter elements are more affected by incorrect assumptions about matrix composition. As for any other quantitative analytical technique, it must be
kept in mind here that the more unverified assumptions are made, the less accurate may be the final quantitative result.

If the sample thickness is larger than about 50 µm, the uncertainty about its value is irrelevant, because from the point of view of PIXE this is actually an infinitely thick target for the quantification of all elements. However, for a target of an intermediate unknown thickness, the quantitative analysis becomes problematic because, in principle, there may be different combinations of composition and thickness leading to the same detected X-ray yields. Some independent guess often may be made on either of the two, thus leading to reasonable results also in this case; however, it must be stressed that this remains the hardest situation to deal with for an accurate quantitative analysis.

### 2.3 Minimum Detection Limits in PIXE Analysis

A high value of the efficiency factor \( \eta \) for a given element, leading to large statistics for the corresponding X-ray peak in the PIXE spectrum (Equation 6), is obviously important for a sensitive determination of that element. However, this is not the only requisite, as the MDL depends on the signal-to-noise ratio.

In general, the performance in terms of the MDLs improves for any analytical method when the signal is detected with higher efficiency and when the noise is low. Because the cross-sections for the production of X-rays by accelerated particles are high, the number of X-rays produced by PIXE per unit quantity of a given atomic species is large. This means that the signal is good. The noise from which the signal must emerge is, in the case of PIXE (as well as in any other spectroscopic technique), the continuous background in the spectra. As can be seen in Figure 2, a continuous background is actually present in the X-ray energy spectra from a PIXE measurement, and characteristic X-ray peaks must be discriminated from the statistical fluctuations of this background. Let us therefore examine in some detail the reasons for the presence of this continuous background and the possibilities for the operator to reduce it.

#### 2.3.1 Background in PIXE Spectra

There are several physical reasons for the presence of the continuous background in the PIXE spectra.

In the lower-energy part the continuous spectrum is higher and arises mainly from atomic electrons ejected by the interactions of the beam particles with the target. During their stopping down within the target, these electrons emit BS radiation. This is a consequence of a basic law of electromagnetism, that when a particle bearing electric charge undergoes an acceleration, it emits energy in the form of electromagnetic radiation. The intensity of the emitted BS is proportional to the square of the acceleration; its energy has a continuous spectrum extending up to the initial energy of the emitting particle. The electron BS in the lower part of the PIXE spectrum is called secondary BS, as opposed to the primary BS produced directly by the protons in their stopping down. It is easy to understand that:

- In PIXE, secondary BS has a much higher intensity than primary BS, which is essentially negligible. The forces responsible for both proton and secondary electron acceleration have equal intensity (being the Coulomb forces of interaction with atomic electrons) but the mass of protons is much larger than the mass of electrons. The proton acceleration and the corresponding BS intensity are consequently much lower.

- The maximum energy of the secondary BS is in the ratio \( 4m_e/M \) to that of the incident particles (with \( m_e \) and \( M \) being the electron and proton mass, respectively), this being the maximum energy transfer from incident particles to free electrons. Indeed, the maximum velocity acquired by the electrons, occurring for central collisions, is equal to twice that of the incident particles, so that Equation (14) holds:

\[
E_{\text{max},e} = \frac{1}{2} m_e v_e^2 = \frac{4m_e}{M} \frac{1}{2} M v_p^2 = \frac{4m_e}{M} E_p \quad (14)
\]

In the case of protons, the maximum energy value of the secondary BS is therefore around 4.3 and 6.5 keV for \( E_p = 2 \) MeV and 3 MeV, respectively. Consequently, under typical measuring conditions the background due to BS is practically zero in the higher part of the energy spectrum, i.e. the region of the X-ray lines used for the quantification of medium- and high-Z elements. This is just the region where X-rays are produced with lower cross-sections by PIXE. Therefore, where the signal is lower, the noise is fortunately lower also, and good MDLs are preserved. Many studies (both theoretical and experimental) have been carried out on the physics leading to the BS emission in PIXE.\(^{[20,21]}\) An important practical feature is that BS emission is not isotropic, but has a maximum at around 90° to the beam direction. Therefore, to improve the performance in terms of MDLs, one should avoid placing the X-ray detector at around this angle. The most frequently used geometry is with the detector as backwards as possible to the beam direction, typically at 135° or more.

Some background continuum exists even in the higher energy part of the PIXE spectrum. It originates mainly from the Compton interactions of the higher-energy gamma rays produced by the incident particles either...
in the target or in other materials before hitting the target (collimators, exit window in the external beam set-up, etc.). Compton interactions produce a partial energy release of the electromagnetic radiation in the material where they occur; the fraction of the full gamma energy that is released depends on the scattering angle in the Compton interaction. The resulting spectrum is therefore continuous and practically flat throughout the energy region of interest for PIXE, i.e. 1–30 keV.

The subject of gamma ray production in a PIXE experiment has been covered in detail. The intensity of Compton background is generally low, and depends on:

- The detector material and active volume. It increases with increasing Z and this is one reason why silicon detectors are in general preferred to germanium ones. As far as the detector’s volume is concerned, in the range of detector sizes that are used, larger ones produce a higher Compton background because of an increased probability of gamma ray interactions within their volume.
- The composition of the target itself and of the other materials with which the beam particles can interact. For low-Z materials, nuclear interactions with the beam protons are much more probable due to the closer approaches of the protons to the target nuclei, which in turn derives from the lower Coulomb repulsion. At the proton bombarding energies used in PIXE, most nuclei of low-Z elements can be excited inelastically and emit as a consequence gamma rays, which produce the Compton background in the PIXE spectra. The intensity of such emissions depends on the element, but also on the thickness of the emitting material and beam energy, due to the existence of resonances in the nuclear interaction cross-sections. Under typical conditions, fluorine and sodium are the elements giving rise to the higher gamma ray yield.

The Compton background arising from the production of gamma rays of elements within the target is unavoidable and the only expedient to lower it is to avoid the presence of unnecessary material around the detector, to decrease the probability of Compton scattering of the gamma rays in the surrounding materials. More can be done instead to decrease the contribution due to gamma rays originating from primary beam interactions on materials other than the target itself. First, low-Z materials such as aluminum should be avoided as constituents of chambers, collimators, scatterers, exit windows (in external beam set-ups), etc. Second, the points along the beam path that may constitute possible gamma ray sources arising from beam interactions should be effectively shielded towards the X-ray detector.

### 2.3.2 X-ray Line Interference

In addition to the presence of the continuous background, there is another factor that may worsen – in specific circumstances only – the MDL of some elements. This problem is common to all analytical techniques based on X-ray spectrometry (i.e. also XRF and EPMA) and it is recalled here just for the sake of completeness. This limiting factor consists of energy overlaps between X-rays originating from different elements. When the energy difference between two X-rays is much smaller than the detector resolution, they can hardly be discriminated by the spectra deconvolution codes. If one of the two elements giving rise to the overlapping X-rays is present in much larger abundance than the other, it can mask the presence of the weaker one even in the case of somewhat larger energy differences, within the tails of the strong peak. Thus, the possibility of detection of the weaker line is considerably worsened. Examples of this problem are:

- \( K_\alpha \) lines of element Z with \( K_\alpha \) of element \((Z + 1)\), for \( 20 < Z < 30 \);
- K line of Na (1.041 keV) with L lines of Zn (1.020 keV);
- K line of Mg (1.254 keV) with L lines of As (1.282 keV);
- \( K_\alpha \) line of S (2.308 keV) with M lines of Pb (centroid at 2.346 keV) and to a lesser extent with those of Hg (centroid at 2.224 keV);
- \( K_\alpha \) line of Ti (4.509 keV) with \( L_\alpha \) lines of Ba (centroid at 4.465 keV);
- \( K_\alpha \) line of As (10.532 keV) with \( L_\alpha \) lines of Pb (centroid at 10.551 keV).

When the interference between two lines cannot be safely deconvoluted, the quantification of the two elements must be done on the basis of other lines of their spectra. This often implies that minor-intensity X-ray lines come into play and the MDL for the corresponding element increases.

### 2.3.3 Minimum Detection Limits

In the light of all the above considerations concerning high X-ray production cross-sections and detection efficiencies, and low continuous background in the energy spectra, it turns out that PIXE is basically a very sensitive technique. Figure 10 gives an idea of the MDLs of some elements. This often implies that minor-intensity X-ray lines come into play and the MDL for the corresponding element increases.
effect: beam energy, beam current intensity, and total time of target exposure to the beam all affect the analytical performance in terms of the MDL. Under certain circumstances, the attainable MDL can be much better than suggested by Figure 10. An example is when searching for ultratrace elements of medium \( Z \) in a very low-\( Z \) matrix. The opposite occurs in the presence of a high abundance of elements that give rise to X-rays interfering with those of the elements searched for.

When dealing with MDLs, both relative (in terms of minimum detectable mass over the total mass of the sample) and absolute values should be considered. Indeed another great quality of PIXE is that absolute quantities as small as picograms of the elements in the detectable range can be quantified in measurements lasting only a few minutes. This makes PIXE a very useful technique when nondestructivity is a mandatory requirement (as in the case of precious items such as works of art), or when the quantity of material to be analyzed is very small (as in some applications related to environmental pollutants).

### 2.4 Ion Accelerators and Sample Irradiation

#### 2.4.1 Beam Production and Transportation

Most of the particle beams for PIXE analysis are produced by small Van de Graaff accelerators, with maximum terminal voltages of 2–4 MV. Accelerators of this kind often exist in nuclear physics divisions of universities or other research institutions, being the equipment used for nuclear spectroscopy studies in the 1960s and 1970s. In these situations the initial cost of setting up centers for IBA and specifically PIXE has been limited to the dedicated irradiation chambers (or the specimen holders for external set-ups, see below) and to the detection systems, which are not especially expensive. This certainly favored, in the 1980s, the start-up of PIXE activities in many laboratories. However, these accelerators are becoming less supported by their manufacturers. A new generation of small electrostatic accelerators (based on voltage generators of both Van de Graaff and Cockroft-Walton type) have been installed in some laboratories either to replace older ones or to start up new PIXE (and other IBA) activities. Most of these new accelerators are of the tandem type. In tandem accelerators, two acceleration tubes are placed on opposite sides of the positive high-voltage terminal, located in the centre of the machine, inside a tank which is gas filled at high pressure (this is needed to avoid voltage discharges to ground). The ions are produced by an external negative-ion source and then injected into the first acceleration tube from the low-voltage side. After acceleration to the positive voltage terminal, the ions undergo a charge inversion through the stripping of the outer electrons (produced by passing the beam through proper thin carbon foils or gas flow), so that they are further accelerated in the second tube towards ground. In this way, a lower terminal voltage is sufficient to produce a beam of sufficient energy. For instance, with a 2-MV tandem, proton beams up to 4 MeV, or \( \alpha \)-beams up to 6 MeV can be produced. Further advantages of tandems derive from the presence of the external ion source (contrary to the case of single-ended electrostatic accelerators, where the ion source must be on the high-voltage terminal inside the high-pressure tank). With different sources, it is possible to accelerate any kind of ions, including the heavier ions that may be used for other IBA techniques. In addition, one can perform accelerator mass spectroscopy (AMS) for the search of ultratrace elements or rare isotopes in a sample. For this purpose, the sample is used as the material to be ionized in the source; the best-known case is the quantification of \(^{14}\)C for archaeological dating. Together, these factors have initiated start-up of several new laboratories (or the modernization of previously established ones) based on tandem machines, where both PIXE and other ion-beam-based applications are performed.

In standard PIXE, the beam from the accelerator is led to hit the sample by conventional beam transportation systems, mostly based on magnetic deflection and focusing. The typical energy stability of beams produced by this kind of accelerator is quite good, with a residual voltage ripple normally less than 1 kV rms at maximum voltage. For PIXE applications this is not a real need, however, because the trend of X-ray production cross-sections with beam energy is rather smooth. Also, the beam currents that the accelerators might produce (up to tens of microamps) are not exploited, due to the large value of the production cross-sections. Typically, PIXE measurements are performed at beam current intensities of 20–30 nA at most (but much less than 1 nA for certain applications in which precious samples might otherwise be damaged by a more intense beam; see section 3).
Thus, in both respects (energy stability and current intensity) the accelerator performance is never a limitation for standard PIXE. This is less true for micro-PIXE set-ups, in which a much higher beam brightness is needed and high energy stability is at a premium. However, the standard performance of typical accelerators is already adequate for micro-PIXE; thus, a new accelerator of special design is not required just to implement a micro-PIXE facility.

The beam transportation line is obviously under vacuum. Typical values are around $10^{-6}$ mbar, although worse vacuum levels may be tolerated for PIXE applications (but not for micro-PIXE). Visual inspection of the beam cross-section is often provided along the beam line by retractable quartz viewers, whose fluorescence is observed through viewports by means of TV cameras. This makes the tuning of focusing and deflection systems much easier. For the same purpose, retractable Faraday cups are often available at critical points along the beam line.

The beam cross-section at the target may need to be either as small as possible (for a microbeam, section 2.5), or larger so as to average over a wider area of interest, which may be even some tens of square millimeters. In the latter case, it is necessary to have a uniform distribution of the beam current intensity over the probed area, in order to correctly average out inhomogeneities in the target composition.

A uniform beam current density can be achieved in several ways. One possibility is to pass the beam through a thin metal foil (some hundreds of micrograms per square centimeter) placed one or two meters upstream. Then the multiple small-angle scattering within the foil widens the angular aperture of the beam, and an adjustable collimator picks up its central, homogeneous part over the desired size. A side effect with this technique is an energy loss and straggling of the beam, but this is not a problem in PIXE and can be perfectly taken into account in the quantitative analysis.

Alternatively, the beam may be defocused by untuning the magnetic quadrupoles present on the beam line for focusing, and then collimating close to the target. Although this technique is simpler, it is less effective because it is difficult to monitor the actual homogeneity of the beam intensity over the selected area. A third method uses a well focused beam, and rasters with an $x$-$y$ scan over the selected sample area. The disadvantage of this technique is that, in the presence of target inhomogeneities, the X-ray count rate from the different parts may vary considerably during the raster. Consequently, the pile-up corrections in fitting the PIXE spectra (section 2.6.2) may become problematic, as the corrections applied by the data reduction software are based on the assumption of a time-uniform count rate.

All collimators along the beam transportation lines are generally made in materials producing no detectable X- or gamma rays. Tantalum is the usual choice far from the target point because of its good dissipation of the heat generated by beam stopping. The production of K-series X-rays (around 60 keV) and of gamma rays due to Coulomb excitation of the nucleus is not intense, whereas copious L X-rays produced are easily absorbed by placing lead shielding in the line of sight to the detectors. Close to the target, the preferred material is graphite, which does not emit X-rays if sufficiently pure.

### 2.4.2 Irradiation Chambers

In conventional PIXE, irradiation is performed with the sample in vacuum. This is a limitation in several important kinds of application, such as when large samples are to be analyzed and taking samples of material is not allowed, or when keeping a specimen in vacuum could alter its composition. To overcome these problems, many laboratories have implemented external beam irradiation facilities (section 2.5).

The irradiation chamber is often made in aluminum, for economical reasons, but this material is not best suited because of its relatively high cross-section for the production of gamma rays. The regions of the chamber (as well as of the interior of the beam line) that are exposed to the beam (due to scattering) should be lined with nonemitting materials, such as ultrapure graphite.

Most chambers have a multisample capability in order to make the analysis faster. More or less sophisticated means of automatic sample changing are available. Usually a glass window allows the operator to view the samples inside the chamber with a video camera, both during samples changing and during irradiation, to check sample integrity under the beam.

The usual detection geometry is with the X-ray detector as backwards as possible, because the secondary BS is lower (section 2.3.1). The X-ray detector may be placed outside the vacuum chamber, viewing the sample through a window made as thin as possible so as to limit absorption of low-energy X-rays. Alternatively the detector cryostat may even be incorporated within the chamber, sometimes with the possibility of a windowless geometry based on a sliding vacuum seal (section 2.6.1). A means of inserting a variety of X-ray absorbers of different thickness and material must be provided, to enable changes to the detection efficiency curve versus X-ray energy according to the specific analytical demands of the experiment (section 2.6.2).

Additional detectors are often present in the chamber to complement PIXE analysis with the simultaneous use of other types of ion-beam-based techniques. These usually include one or more surface barrier silicon detectors.
with which to implement backscattering spectroscopy. When using protons as projectiles, it is not always safe to assume “Rutherford” elastic scattering as valid, i.e. cross-sections may not always be computed from purely Coulomb projectile–nucleus interactions. In the proton elastic scattering on light-Z elements, the effects of the nuclear force on cross-sections may be nonnegligible or even dominant, due to the close approaches that can take place between protons and target nuclei. In spite of this, however, useful quantitative information can be extracted (corroborating and sometimes adding to that obtained by PIXE), provided that experimental data (including the nuclear interaction effects) are available for the cross-sections. Inelastic scattering can also provide useful information. A germanium detector may be faced to the irradiation chamber for the simultaneous detection of gamma rays: PIGE. Because gamma ray energies are much higher than X-ray energies, and consequently the absorption of electromagnetic radiation is not a problem, the germanium detector need not be placed inside the chamber.

2.4.3 Measurement of Beam Current and Charge Integration

During an irradiation, it is important to monitor the beam current because the sample may be damaged if safe levels of intensity are not maintained. The safety level varies with sample types, being much lower in general for electrically and thermally nonconductive materials. Equally important is accurate integration of the beam current during each run, as this is often a fundamental parameter for correct quantification of the obtained data (see Equations (3), (6), and (13)).

With thin specimens that allow the beam to pass through them with negligible energy loss, the traditional technique may be used of both measuring and integrating the beam current in a Faraday cup. The cup must be obviously insulated from the beam line. The cup material or lining must be such as to avoid emission of detectable X- and gamma rays, for the same reasons given above for the materials of beam line, collimator, and irradiation chamber. Typically graphite is used. Care should be taken that the cup receives all the particles that have traversed the beam; with samples of intermediate thickness, a relevant overall scattering may occur and the Faraday cup geometry must ensure an adequate acceptance angle. Also, the phenomenon of secondary electron escape from the cup may be relevant, which could give rise to an overestimate of the actual beam current. To prevent this effect, a negatively charged ring may be used as a guard electrode at the entrance to the cup, to reject outgoing electrons. Alternatively they can be deflected and thus recollected through the use of small magnet assemblies (electrical bias and small magnets will not affect the much heavier and energetic incoming particles). An accuracy as good as 1% can be achieved through the use of good-quality current meters and charge integrators.

With thick samples that stop the beam, the current must be measured and integrated on the sample itself, which requires the samples to be made electrically conductive if not already so (in order to avoid sample charging and consequent abrupt discharges). This may be achieved by a thin surface carbon coating, as in the case of EPMA. Secondary electrons escaping from the sample may be a much more relevant effect than with Faraday cups, due to the open geometry; they must be recollected by using a negatively biased suppressor electrode at a few hundred volts potential. Alternatively, the target itself may be positively biased with respect to the chamber.

With thick samples – or even with samples of intermediate thickness, causing a large scattering of the beam – alternatives to the Faraday cup may be used to measure the beam current. A thin self-supporting foil can be inserted along the beam path before the sample, and the count rate of backscattered particles, measured by a proper particle detector, can be taken as an indirect measurement of beam current intensity. Alternatively, the yield of some other interaction product of the beam particles with the foil material – such as X-rays themselves – may be used as an indicator of the beam current. In some external beam set-ups, the beam line exit window itself is used. When using such procedures, the problems of correct quantification of the current connected to secondary electron emission are completely overcome. After a calibration they may even provide a good absolute measurement of the current, provided that the metal foil does not change its thickness during irradiation due to beam-induced damage. A variant of this method is to measure the yield of backscattered particles (or other beam-induced radiation) on a rotating vane intercepting the beam at a sufficiently high frequency that, at the end of the measurement, the current sampling procedure is significant. Typically, 1 Hz is sufficient since run times are of the order of minutes.

2.5 External Beam Set-ups

An increasingly popular variant of conventional PIXE is external or “in-air” PIXE. This, as well as other IBA techniques, can be performed simply by passing the particle beam through a thin window, thus hitting the sample in its natural environment. The beam size can be determined by an aperture in the last section of the beam path within the vacuum, whereas the X-ray detectors are external. The sample is placed a few millimeters from the window and, by using a positioning stage (sometimes with micrometric control), can be moved in the plane.
NUCLEAR METHODS

The external environment is often saturated with helium, to reduce beam energy loss and straggling with respect to air. The helium may be simply flooded in front of the exit window, with no containment, or be held in a simple closed environment. The use of helium has the further significant advantage that the transmission of low-energy X-rays is much higher than in air, which increases the possibility of detecting lighter elements. As an example, more than 96% of the 1.04-keV K X-rays of sodium are still transmitted when traversing 3 cm of helium, whereas for a similar distance in air the transmission would be only $2.4 \times 10^{-6}$; for the X-rays of sulphur (2.31 keV), the transmissions in 3 cm of helium and air are 99.7% and 28%, respectively. A disadvantage is that helium can penetrate the thin beryllium window of the Si(Li) detectors (section 2.6.1). This produces a progressive worsening of the vacuum levels inside the cryostat, which may necessitate a pump and bake procedure, typically after some months of use. To overcome this problem, the use of hydrogen rather than helium has also been reported (detector windows are much less permeated by the hydrogen molecules), but has not gained popularity for the fear of accidents due to its inflammability.

Figure 11 is a sketch of a simple external beam set-up, with helium flooding in an unenclosed environment and two Si(Li) detectors.

Topics relevant to external beam analysis have been reviewed in several articles. (23–25)

The main advantages of an external beam set-up are:

- ease of handling and changing of the sample – even large objects may be analyzed, and the specimen positioning is not problematic;
- drastically reduced risk of beam-induced damage to the sample – the problems of local heating are much smaller, especially when using a helium flow, which is a very efficient heat remover;
- electrical charging of insulated samples does not occur – this avoids the need for surface coating by graphite, as is usually done with samples in vacuum;
- ease of installation and change to the set-up (type, number and position of detectors, tilting angle of the sample, provisions for monitoring camera, etc.).

The first three of these points have encouraged the use of external beam set-ups for the analysis of fragile and/or precious objects, such as items of artistic, archaeological, and historical interest (sections 3.4 and 3.5). However, the external beam set-up is advantageous for most PIXE applications. Only for applications requiring a microbeam below about 10–20 µm is the external beam set-up not appropriate. Indeed, the scattering in the window and in the external path produces a beam halo. Thus, even with the best focusing, the actual beam spot size on the target cannot be smaller than a minimum value (depending on several factors, mainly the distance travelled by the beam in atmosphere). Some inconvenience with an external beam may also arise for other IBA techniques, such as Rutherford backscattering spectroscopy (RBS) or nuclear reaction analysis (NRA), when operated simultaneously with PIXE. As in those techniques the accuracy of the analytical information is directly related to the beam energy, the energy straggling due to the exit window and to the residual path in the atmosphere worsens the quality of the data obtained. However, in the late 1990s thinner beam exit windows have become available (see below). This, and the use of helium outside the window, has enabled the advantages of the external beam set-up to be retained without excessive drawbacks.

In external beam set-ups, the exit windows for the beam must be mechanically strong enough to sustain the pressure drop from the vacuum environment of the accelerator beam lines to atmosphere, and also exhibit a high resistance to radiation damage. Certain materials, such as Mylar®, which are mechanically strong enough, cannot tolerate even weak beams without early rupture. A typical material for beam exit windows is Kapton®, a polymer of composition $(C_{22}H_{10}N_2O_4)_n$. At a thickness of 8 µm, Kapton® typically withstands a beam of 10 nA with a cross-section of 1 mm² for 2–3 days, after which a change of the window is a wise precaution. The energy losses in
8 µm of Kapton® are 90 keV and 125 keV, respectively, for 3 MeV and 2 MeV protons; the fwhm energy straggling is about 20 keV (uncorrected Bohr estimate). Further energy loss and straggling before hitting the target are typically of the same order in air, or much smaller in helium. The overall values for both the energy loss and straggling (the former sum up linearly, the latter combine quadratically) are therefore of little consequence to PIXE, due to the smooth trend of X-ray production cross-sections with beam energy. Therefore, the possibility of a quantitative analysis is fully retained with external PIXE.

Another material sometimes used for exit windows is aluminum (about 10 µm thick), with a durability of months before changing the window. However, a higher continuous background is produced in the spectra due to beam-induced gamma rays from the window. Its use is therefore not recommended when bombarding very thin samples, where the X-ray yield is relatively weaker. With thick samples, an aluminum window may be a good choice.

The successful use of ultrathin windows of Si₃N₄, available down to a thickness of 0.1 µm, has been reported. This material exhibits a very high resistance to the beam and the thin foils still withstand the pressure drop for a surface area of a few square millimeters. It has been employed therefore to extract focused proton microbeams down to 20 µm, with negligible halo due to the extreme thinness and to a very compact geometry with the specimen quite close to the window, in a helium atmosphere.

2.6 Detection of X-rays, Data Acquisition and Reduction

2.6.1 Working Principle and Characteristics of Si(Li) Detectors

Typical detectors used in PIXE are lithium drifted silicon crystals acting as diodes. In these solid-state nuclear detectors a free charge-depleted volume is created on one side of the junction by applying a reverse bias with a convenient high voltage power supply (some hundreds of volts, up to 1 kV). The ionizing radiation that interacts in this volume produces free hole–electron pairs that are promptly swept by the electric field – due to the voltage bias – towards the collecting electrodes. As the number of electron–hole pairs created inside the active volume is proportional to the energy release of the ionizing radiation (an average energy value of 3.6 eV is needed to create a hole–electron pair), the total charge collected on the electrodes is also proportional to the released energy. The current pulses through the detector produce, at the preamplifier output, voltage steps of amplitudes proportional to the energy releases. These voltage signals, when appropriately amplified and shaped, are then amplitude-analyzed to construct the detected X-ray energy spectra (section 2.6.2).

The Si(Li) detectors must work at a low temperature (typically −170 °C). Otherwise, when voltage biased, the inverse current of the diode (increasing exponentially with increasing temperature) would damage the detector itself and/or the first stage of signal preamplification. In particular, the compensation due to the presence of the drifted Li ions might be lost in a short time due to their mobilization (induced by the electric field). Si(Li) detectors can instead be safely stored at room temperature when they are not under bias. Protection circuits should always be used (and are indeed available in modern detectors) to prevent the high voltage supply from actually applying the bias until a sufficiently low diode temperature is reached.

Because of the need for a low operation temperature, the crystals are kept inside a cryostat under vacuum and cooling is typically achieved by conduction through a cold finger kept in contact with liquid nitrogen in a Dewar. The option of a Peltier cooling system is also available, which makes the assembly much more compact at the expense of less-effective cooling (which implies a slightly worse energy resolution). A vacuum is first created in the cryostat at time of manufacture. A proper amount of molecular sieves, in thermal contact with the cold finger within the cryostat, passively maintain a sufficient level of vacuum when the detector is cooled. In general, this situation may be maintained for several years, after which servicing (pump and bake procedure) is needed to restore the vacuum.

The cryostat wall in front of the detector (the entrance window) must be very thin if low-energy X-rays are to be transmitted with negligible probability of being absorbed by the window itself before reaching the detector’s active volume. The window should also be light-tight because silicon detectors are photosensitive, producing a large response to ambient light. Traditional cryostat windows are made of beryllium, of a thickness down to 8 µm. They can stand the pressure drop over a surface area of about 1 cm², but they must be handled with great care because they are very fragile. Any puncture of the window may be catastrophic, with sudden ventilation of the detector’s cryostat. This in turn may have very serious consequences in that the detector system can be destroyed if the diode was under bias – the sudden vapor condensation on its surface gives rise to current paths, which may spoil the passivated surface that maintains the bias voltage. In addition, the large currents may burn the entrance FET (field effect transistor) of the preamplifier.

Typical active areas of the Si(Li) detectors are from 10 to 100 mm² and the thickness of the depleted volume is from 3 to 6 mm. As far as the intrinsic efficiency
\[ \epsilon_{\text{det}} \text{ is concerned (see Equation (4) and the following discussion), Si(Li) detectors have a 100\% intrinsic efficiency over an X-ray range from 2–3 keV to about 20 keV. This means that in this energy range an X-ray reaching the entrance window will lose all its energy in interactions inside the active volume, thus producing a full-energy peak in the spectrum. Figure 12 shows the intrinsic efficiency of typical Si(Li) detectors as a function of X-ray energy, for various entrance windows and detector active thicknesses. The detection efficiency decreases at both lower and higher energies. On the high-energy side, this is in connection with the limited active thickness of the detector – with smaller detector thicknesses and higher X-ray energies, the probability of losing all the energy within the active volume decreases. On the low-energy side, the intrinsic efficiency decrease is due to the increasing probability of X-ray absorption in the detector entrance window.}

\[ \text{Materials other than beryllium have also been used to build extra-low absorption windows that make the detection of very light elements possible, down to carbon. An alternative when the operator wishes to extend analysis to these elements is the possibility of window removal. This option can only be used when working with an in-vacuum set-up, and through some mechanical design to allow for vacuum-tight insertion of the cryostat inside the irradiation chamber. Removal of the window can only be done once a sufficiently good level of vacuum is reached in the chamber, in order to avoid vapor condensation on the cold detector surface.}

\[ \text{It should be remembered that the severe problems of self-absorption within the sample itself (section 2.2.2) for the very-low-energy X-rays involved in the detection of these light elements (276 eV for carbon) makes their analysis only qualitative anyway. This consideration is more critical the lower the atomic number. As a general rule, relatively good quantification can be made only when starting from Na (} E_X = 1041 \text{ eV}); however, this also depends on the kind of sample (whether it is extremely thin or not, the nature of matrix, etc.) and on the degree of accuracy required.}

\[ \text{Besides the effect of the cryostat window, at lower X-ray energies the detection efficiency is very sensitive to any absorption layers introduced intentionally or due to dead surface layers on the detector. The latter may occur when the vacuum level inside the cryostat worsens because of small leaks – a layer of condensed vapor is formed on the front surface of the cold detector inside the cryostat. Low-energy efficiency can also be drastically reduced by purposely interposing absorption filters along the path from target to detector. For example, with a Mylar® absorber of only 10-\mu m thickness the transmission of the 1.04 keV X-rays of Na is 3.3%, that of the 1.74 keV X-rays of Si is 47%, that of the 2.3 keV X-rays of S is 72%, and 92% of the 3.69 keV X-rays of Ca are transmitted. With 100-\mu m of Mylar®, transmissions are } < 10^{-14}, 0.05\%, 5.5\%, \text{ and } 43\%, \text{ respectively, for the X-rays of the four elements. It is obvious that by using different absorber material and thickness one can drastically modify the curve of detection efficiency versus X-ray energy. As explained in section 2.6.3, this property is often exploited to make the MDLs more homogeneous over a wider range of } Z. \]

\[ \text{2.6.2 Spectra Acquisition and Data Reduction}

\[ \text{The voltage signals produced by the charge preamplifiers are first shaped and amplified to make them suitable for amplitude classification, which is the basis for the acquisition of the energy spectra. A quasi-Gaussian pulse shape is normally used, which can be synthesized by different linear networks including successive stages of differentiation and integration of the original quasistep signal from the preamplifier.}

\[ \text{The time constant used must be long enough to allow for complete collection of the charge created by the ionizing radiation inside the active volume of the detector. Incomplete charge collection would result in the so-called ballistic deficit effect, which produces low-energy tails to the line shapes in the energy spectra, increasing linearly with peak energy. Also, because of the prevalence of series noise, long time constants favor a better signal-to-noise ratio, i.e. better energy resolution.}

\[ \text{At the same time, the time constant should be short enough to avoid a long time occupancy of the signal baseline by the pulse, in order to make handling of higher count rates possible. For the usual quasi-Gaussian pulse shapes a baseline recovery to better than 1\% is achieved in a time equal to 3–5 times the time constant.} \]

**Figure 12** Intrinsic efficiency of Si(Li) detectors versus X-ray energy. The three curves on the left side refer to detector entrance windows of different thickness; the two curves on the right refer to different overall thickness of the detector’s active volume. (Reproduced by permission of EG&G Ortec.)
When the average time interval between successive pulses gets smaller than about 10–20 times the baseline occupation of a single pulse, there begins to be a non-negligible, increasing probability that a pulse arises before the previous one has completed its recovery to the baseline. This generates a wrong classification of the pulse amplitude (the pile-up effect) with consequent distortion of the accumulated energy spectra. Minor distortions may also be generated by imperfect tunings of the electronic chain, such as improper adjustment of the pole-zero cancellation or of the baseline active recovery circuits.

The choice of time constant is dictated by the main requirement in terms of performance (as outlined above, high count rate capability and good energy resolution are somehow conflicting). In general, a compromise between the two needs is given by a time constant value of 6–10 μs, but longer values also may be used when extremely good resolution is the main goal and the low count rate makes this possible. Of course, everything depends on the specific experimental situation – target composition and thickness, beam current, detector size and geometry, etc.

The linearly shaped pulses are amplitude analyzed by an analog-to-digital converter (ADC), which is then coupled to a computer where a distribution histogram of the digitized amplitudes is constructed. Because all the signal handling processes are linear, the histogram represents the spectrum of the radiation energy losses inside the detector. Thus, the full-energy X-ray interactions give rise to peaks in the spectrum. The energy scale of the spectrum can be calibrated by using a source of X- or gamma rays of known energies for a spectrum acquisition.

To extract quantitative information about elemental abundance in the sample, the peak areas in the X-ray energy spectra must be evaluated as accurately as possible. The various aspects of the spectrum deconvolution procedures are essential for quantitative analysis. In particular, modeling of the continuous background shape and deconvolution of peak multiplets have been widely studied. Several software packages are available to the analyst, including provisions for taking thick target matrix effects into account. Extended reviews of these aspects are available.\(^2,^7\)

The first step of the process is in general the modeling of the background. As the background is higher in the lower-energy X-ray region (section 2.3.1), where in addition the X-ray density (and hence the probability of overlaps) is higher, this is the most crucial energy region to be considered. Basically, two different strategies may be adopted: the assumption of an analytical (in general polynomial) function for the shape of the continuum; and an empirical subtraction of its contribution by a smoothing–filtering procedure that eliminates the variations of the counts per channel that are slower than a preset value. To be considered as not arising from true lines, these variations must meet certain criteria, which take into account the amplitude of the statistical fluctuations and the assumed peak widths. Once the contribution of the continuous background has been eliminated by this filtering procedure, the peak areas are determined from the filtered spectra (rather than from the direct spectra).

For the purpose of the detection of peaks, even in the presence of multiplets, and of the evaluation of peak areas, two aspects are essential: (a) knowledge of the detector’s response to a single line, i.e. the peak shape; and (b) access to a complete and accurate database of X-ray energies and relative intensities for all the elements in the periodic table, so that after energy calibration the peaks can be assigned to the corresponding elements.

Considering the first point above, the line shapes of the full-energy X-ray peaks in the spectrum are basically Gaussian. The effect of electronic noise that adds randomly to the signal pulse height, and the stochastic nature of the process of electron–hole pair creation in the detector’s active volume both contribute to this shape. X-rays losing identical energies inside the active volume do not always produce exactly the same number of pairs, and this fluctuation in turn results in voltage pulses of variable amplitudes and therefore in peak widening. Due to the statistical nature of pair production, this contribution to the fluctuations is proportional to the square root of the number of electron–hole pairs created, i.e. of the energy loss. The total width of a peak in the X-ray spectrum is then given by an expression such as Equation (15),

$$\Delta E = \sqrt{A + BE_X}$$

where \(A\) is the square of the electronic noise contribution, \(B\) is the square of the so-called Fano-factor relating fluctuations to the square root of energy loss, and \(E_X\) is the X-ray energy corresponding to the peak. This behavior of \(\Delta E\) versus X-ray energy is taken into account when deconvoluting complex spectra.

However, the actual spectral line shape may be more complicated than Gaussian if ballistic deficit and/or pulse pile-up effects are present. Even in the absence of these effects, for high precision deconvolution an accurate representation of the detector’s response is needed. Even minor effects give rise to lineshape distortions, which have to be taken into account, in particular to properly detect and quantify small peaks on the tails of larger ones. Figure 13 illustrates the main contributions to the lineshape. Several deviations from the ideal Gaussian shape can occur to a larger or smaller extent depending on the specific detector.\(^25\)

A major effect that must be mentioned is the presence of an additional satellite peak – an escape peak – at an energy lower by 1.74 keV than the full energy peak.
which may be important to an evaluation are: mistakes between an escape peak and a full-energy peak not properly taken into account. Examples of possible rise to some confusion in the spectra deconvolution if overlap the full-energy peaks of other elements, giving and intensity of the escape peaks because they may 10 keV. It is important to keep in mind the presence peak falls from about 1% at 5 keV to about 0.1% at relative intensity of the Si escape peak to the full-energy by fluorescence are recaptured within the crystal. The resulting K-series X-rays of silicon (1.74 keV) may then escape the detector before releasing their energy to the crystal. In these cases, the total energy released to the crystal is 1.74 keV below the primary X-ray energy. The relative intensity of the escape peak with respect to the corresponding full-energy peak increases with decreasing X-ray energy. This is because the average depth of interaction of the primary X-ray from the detector surface is lower at lower X-ray energies, and it is then less probable that the silicon X-rays produced by fluorescence are recaptured within the crystal. The relative intensity of the Si escape peak to the full-energy peak falls from about 1% at 5 keV to about 0.1% at 10 keV. It is important to keep in mind the presence and intensity of the escape peaks because they may overlap the full-energy peaks of other elements, giving rise to some confusion in the spectra deconvolution if not properly taken into account. Examples of possible mistakes between an escape peak and a full-energy peak which may be important to an evaluation are:

- Ca Kα escape (3.69 – 1.74 = 1.95 keV) with the P Kα line (2.00 keV)
- Cr Kα escape (5.41 – 1.74 = 3.67 keV) with the Ca Kα line (3.69 keV)
- Fe Kα escape (7.05 – 1.74 = 5.31 keV) with the Cr Kα line (5.41 keV).

2.6.3 Optimization of Detection Limits over a Wide Range of Z

As discussed in section 2.2.1 (Figures 7 and 8), the physics of X-ray production in PIXE unbalances the detection efficiency in favor of the low- and medium-Z elements. This holds true even after using the favorable circumstance that L-series rather than K-series X-rays can be used for the quantification of higher-Z elements. This unbalance is a problem when detection of low or trace quantities of high-Z elements is required in the presence of a lower-Z matrix. Figure 7 shows that, if the count rate due to the low-energy X-rays emitted by low-Z elements is kept within tolerable limits, the total number of counts of X-rays from medium- and high-Z elements is too small within reasonable measurement times. In this situation two strategies may be adopted.

The first uses two X-ray detectors simultaneously, which complement each other in terms of the efficiency curve and the solid angle covered. One detector is chosen to cover the widest possible solid angle (which increases efficiency regardless of the X-ray energy), but is prevented from obtaining a large count rate from low-energy X-rays by shielding its surface with an absorber of appropriate thickness (this reduces the efficiency for just the low-energy X-rays). This detector is thus optimized for the medium- and high-Z elements but, due to the absorber, it is practically blind to the lightest elements (see the efficiency curve in Figure 8). The second detector, with no absorber but covering a much smaller solid angle, is then used to simultaneously provide analytical information concerning the low-Z elements. This case is represented by the efficiency curve of Figure 7. The combined effect of the two-detector system, when both L- and K-series lines are used, is that a much broader range of Z is covered with more homogeneity in the detection efficiency.

By changing the absorber on the higher-Z detector and the solid angle of the lower-Z detector (by using appropriate collimators), it is possible to optimize the global detection efficiency over the two detectors to the widest range of Z, tailored to the particular analytical problem (which trace elements are of interest, the matrix composition, etc.).

A cheaper alternative to a two-detector system is the use of a so-called funny filter on just one detector. A funny filter is a nonhomogeneous absorber, which can be constructed from a stack of foils having central apertures of different sizes. In this way different absorptions can be achieved for different solid angles. Thus the detection efficiency for higher-energy X-rays (which are little or not at all affected by the presence of the absorption layers) can be actually made larger than for the lower energies. In other terms, referring to Equation (7), the parameter Ω becomes an increasing function of X-ray energy, getting higher for higher-Z elements. A judicious choice of the funny filter geometry and composition can compensate effectively for the drop in X-ray production cross-section at higher Z. The drawback is that the actual shape of the function η versus E becomes more irregular than with a homogeneous absorber (or no
PIXE (PARTICLE-INDUCED X-RAY EMISSION)

explicit absorber). This results in a more difficult modeling of the efficiency curve $\eta(E_X)$, which in turn is essential to obtain accurate quantitative results with PIXE. In practice, when using a funny filter a large number of standard reference samples (one for each element over a much larger $Z$ range) is needed to experimentally determine the detailed behavior of $\eta(E_X)$. Even so, the uncertainty remains larger because the impact of possible inaccuracies in the knowledge of the areal densities of the individual standards is no more attenuated by the effect of “averaging” with neighboring-$Z$ standards that is instead allowed when in the presence of a smooth behavior with $Z$.

2.7 Micro-PIXE

Depending on the specific analytical problem, one may need a relatively large size of probing proton beam (up to tens of square millimeters, when it is necessary to get an average composition on a wide surface), or a very small one (when the surface distribution of the elemental concentrations has to be mapped with the highest possible detail). When the beam diameter is reduced to about 100 $\mu$m or less, one generally talks about microbeams. In the simplest microbeam set-ups, the cross-section of the beam on the target is defined by collimation, by placing slits or apertures upstream, not far from the target. By this procedure, beam sizes as small as 100–200 $\mu$m can be obtained; this represents a sufficiently small size for many applications requiring detailed information on spatial distribution of elemental concentrations.

Sometimes an even smaller beam cross-section is necessary, and any further reduction of the beam size by brute collimation is no longer effective. At very small apertures, scattering of the particles by the slit or collimator edges produces significant beam halos over an area larger than that geometrically defined by the aperture. To obtain beam sizes down to 1 $\mu$m or below, strong focusing is necessary. The production of well-defined and sufficiently intense beams (1 nA of proton current is not exceptional) of the order of 1 $\mu$m is now a standard feature of set-ups based on strong focusing and the technical aspects of these set-ups have been widely reviewed.\(^{29–31}\) Essentially, a microbeam is obtained through a beam-optics system which includes an object (a small, micrometrically adjustable slit aperture illuminated by the beam from the accelerator) and a set (doublet, triplet or quadruplet) of magnetic quadrupoles acting as a whole on the particle beam as a positive lens. The beam is focused on the target (image of the system), the distance of which from the quadrupoles is much smaller than the object–lens distance. In this way, high demagnification is obtained. In order to reduce the geometrical aberrations, the beam divergence at the entrance of the quadrupole system is strongly limited by collimator slits (Figure 14).

Almost invariably, the microbeam facility includes a system to fast scan the beam two-dimensionally over the sample, with a raster area having sides of the order of up to several hundred micrometers. This is accomplished by magnetic deflection with coils prior to the quadrupole focusing. Figure 15 is a photograph of the final section of a proton microprobe, including collimator slits, scanning coils, triplet of magnetic quadrupoles and irradiation camera, with micrometric adjustment of the target position and viewing microscope from outside.

In the presence of scanning coils, data acquisition is performed in the so-called list-mode. This means that when an X-ray is detected, a triplet of data is stored: the X-ray energy and the two coordinates of the beam spot position at the detection instant (deduced by the current values of the scanning coils at the instant of X-ray detection). The analysis of the triplets, which can be performed on line, includes the possibility of obtaining elemental maps (plotted as the number of detected X-rays of any given energy as a function of position over the whole scanned area). Alternatively, it is possible to
reconstruct the X-ray spectrum detected over any portion of
the scanned area (down to pixels that correspond to
the limits of lateral resolution, i.e. to 1 µm or even less).
This is similar to the result of EPMA; however, the better
MDLs offered by PIXE (section 1.3.1) make it possible
to extend elemental mapping even to trace elements.

When pushing the limits of lateral resolution to their
extremes, a number of factors come into play which limit
the possibilities of obtaining ever smaller beam spot sizes.
First, the complex aberration effects of the probe-
forming lens system have to be diagnosed and minimized.
These include:

- astigmatism, due to the lack of cylindrical symmetry
  of the quadrupoles;
- higher-order multipole contamination of the quadru-
pole field, deriving from inaccuracies of construc-
tion of the quadrupoles (deviations from fourfold
  symmetry);
- spherical aberrations, coming into play only if higher
currents are needed, which implies the acceptance of
a larger beam divergence;
- rotational, translational and tilt misalignments of the
  quadrupole multiplet assembly.

Second, external sources can also produce broadening
of the beam spot. Among these, an important role is
played by the accelerator characteristics:

- beam brightness at the object slits, which in turn
depends on many factors connected with the ion
source, accelerator, and up-stream beam optics
design;
- accelerator energy instabilities, which produce the
equivalent of chromatic aberrations.

Other relevant factors affecting the quality of the
microbeam are:

- scattering phenomena, both at the slits and due to
  residual gas in the beam line due to poor pumping;
- stray electromagnetic fields that may be caused by
  several sources in the vicinity of the beam line
  (transformers, motors, power supplies, etc.);
- mechanical effects such as vibrations (e.g. induced by
  pumps) in the target area, or even slow drifts of the
target during irradiations, such as those caused by
thermal effects.

One final point concerning PIXE with proton micro-
beam set-ups is that although a lateral resolution as
small as 1 µm or less can be obtained, one should not
forget that the depth investigated by PIXE at standard
bombarding energies (2–3 MeV) is up to some tens of
micrometers (sections 1.3 and 2.2). Consequently, in thick
targets the compositional information is an averaged
value over a larger size. Thus full advantage of ultrahigh
lateral resolution is only obtained with very thin targets
(such as with certain biological specimens), or in samples
where the elemental map of the surface layer is also
representative of the structure in depth (as in the analysis
of electronic devices).

3 SURVEY OF THE MAIN ANALYTICAL
APPLICATIONS

The analytical applications of PIXE are innumerable.
Regular international conferences are held to give
scientists of the IBA community the opportunity to
exchange ideas on the technical developments of PIXE
(improved databases of fundamental parameters, detec-
tion systems, data reduction codes, etc.), and on new
analytical applications. New ideas continue to be pro-
posed, especially when PIXE is combined with other
IBA and nonIBA techniques, which is performed more
and more. The following discussions outline some gen-
eral considerations concerning groups of applications,
with no claim to being exhaustive. The intention is
to point out the peculiar analytical aspects of PIXE
that are specifically important in each of the main
applications.

3.1 Environmental Pollution Studies

These applications were among the first to be successfully
performed during the early years of PIXE development.
Both water pollution and air pollution are currently
investigated, with more emphasis on the latter. The
importance of aerosol analysis is obvious, both in
view of air quality assessment in urban and industrial
areas (impact on the health of humans, animals and
plants), and as a tool in the investigation of general
atmospheric phenomena such as short- and long-distance
air transportation, visibility, and climate.

Since the early stages of aerosol investigations by PIXE,
several reasons for a widespread use of this technique
became apparent.

- Variations in the atmospheric aerosol composition
can take place over very short timescales (of the order
  of an hour) or on longer, seasonal, timescales. The
same applies to spatial variations: air transportation
and deposition phenomena can produce extremely
different results depending on the site of measure-
ment. This large variability calls for vast numbers
of analyses, and a method such as PIXE, capable of
yielding fast quantitative results, lends itself to these
investigations much better than does conventional chemical analysis.

- All elements are potentially important in aerosol analysis, because many can be toxic, and because any compound, bound in particles of the appropriate size, can have an effect on visibility (by the scattering of light). Also, the simultaneous detection of groups of elements, occurring in particular ratios, can be a signature of the source of pollution. Their detection at different sites may constitute an important indicator of long-range air transportation phenomena. In performing the necessary multi-element quantitative analyses, the PIXE method offers advantages in terms of time and cost, with respect to chemical methods or optical spectroscopies. Particularly important is the possibility of complementing PIXE with the simultaneous use of other IBA techniques to extend the range of detectable elements, especially the lighter ones.

- The total quantity of aerosol mass available for compositional analysis is quite small. Typical aerosol mass concentrations in air range from a few to over one hundred micrograms per cubic meter. Traditional ways of collecting aerosol are by filtration over long periods of time, using large pumps and large-size filters in order to collect at least one or two milligrams of aerosol for the analysis of only some elements or compounds. The sensitivity of PIXE, for which overall quantities of about a microgram are adequate for a multi-element analysis, considerably reduces collection times and makes the use of much smaller pumping set-ups possible.

- It is important to obtain separate information on the composition of aerosols of different sizes. The particle size distribution is not homogeneous, and the relevance of particles of different sizes is quite different. As far as the impact on health is concerned, this is clearly connected to the penetration of particles into the breathing apparatus, with smaller ones reaching deeper levels and therefore being potentially more dangerous. As to visibility problems created by aerosols, the size-dependence of their effect, being connected to the scattering of light, is even more obvious. Finally, the size distribution also provides information on the sources of pollution. For all these reasons, sampling methodologies providing size-fractionation of the aerosol are highly desirable. These have been developed using inertial impactors that exploit the differing inertias of different sized particles when following air flow paths in special collectors. These samplers may also provide time-sequence deposition of the size-fractionated aerosol on streaks (typically, about 1 cm high) whose total length may correspond up to 1 week of aerosol collection or even more; each section of about 1 mm width corresponds to a short sampling period of typically 1 h. PIXE can be used to analyze these sections selectively, thereby reconstructing the time behavior of the aerosol composition. The overall quantity of aerosol deposited on each section is minute, typically of the order of 10 µg. The high absolute sensitivity of PIXE is therefore exploited to the highest degree. No other technique enables the analyst to obtain such a high time-resolution of the variation in aerosol composition, with simultaneous sensitive detection of a very large number of elements in runs lasting a few minutes. In addition, after PIXE measurements the samples remain available for alternative analyses, to corroborate or complement the data obtained by PIXE.

- The analysis of aerosol collected on “traditional” filters is also important. Daily sampling with these filters is routinely performed by public authorities in many western cities, but in most cases the only parameter measured is the total mass of aerosol deposited over the day. The collected aerosol is analyzed compositionally only for specific campaigns aimed at obtaining information about a few specific components; in these cases, with traditional analysis, the samples are destroyed. The nondestructive PIXE analysis of time sequences of these filters allows instead the trend of air pollution to be followed over long timescales without losing them for further tests. The reconstruction of aerosol composition has been reported in urban environments for periods of months or years.

Let us now summarize the typical procedure for a PIXE analysis of aerosols.

After sampling on streak (for high time-resolution analysis), or on one-day filters (for studies of trends over long timescales), proton irradiation is performed with runs typically lasting a few minutes per sample.

For the analysis of streaks, the “sample” is each section of the streak and use is made of relatively small-size beams (typically 1 mm; microbeams are not needed). After completion of a run, the next section is immediately exposed to the beam by simply shifting the streaker by the proper distance, often in an automated process. For the daily filters, larger beams (made homogeneous over their cross-section by one of the methods outlined at the
end of section 2.4.1) are used and/or scans are performed over the whole area.

The currents used are typically 5–40 nA. Both in-vacuum and external beams have been used for this kind of measurement. External beams are preferable both to facilitate positioning, changing and/or scanning of the samples, and to minimize the risk of selective loss of some aerosol components when under the beam.

The spectra are normalized to the integrated beam charge on a Faraday cup behind the sample (the aerosol deposit plus substrate are thin enough to let the beam pass through), or to alternative normalization parameters (section 2.4.3).

The deduction of areal densities of the different elements on the deposit is then performed by simple comparison with thin standards. In the thin-target approximation, only the very lowest-Z detected elements may be slightly underestimated, due to the onset of self-absorption effects (section 2.2.2) within the particle grains. The latter effects can be of some relevance (up to 50%) only for the larger-size fraction of the particulate and for elements from Na to Si. However corrections can be applied, and/or these elements may be simultaneously detected by alternative IBA techniques, such as particle-induced gamma ray emission (PIGE), which also may produce data on lower-Z elements undetected by PIXE, such as fluorine.

The elemental concentration in the air is finally obtained through knowledge of the sampling parameters (area of pumping aperture, flow rate, duration of sampling).

In a typical collection campaign, the amount of data accumulated is huge (30–40 elemental concentrations from each sample, separation according to particle size, hundreds of streaker sections (or daily filters) analyzed). Therefore, a statistical analysis must be performed. Principal component analysis (PCA) or factor analysis (FA) are routinely performed on the data sets. These processes group the detected elements into factors according to the similarity of the behavior over time of their concentrations, thereby indicating pollution sources, reconstructing their relative weights in the total particulate mass, and also disentangling possible contributions from different sources to the same element.

Owing to the large amount of data that can be collected in a relatively easy way, large-scale monitoring of environmental quality makes wide use of PIXE data. For instance, the US monitoring network “IMPROVE” is largely based on PIXE-determined elemental concentrations in air.

Hundreds of papers have been published on PIXE measurements of aerosols. Specific results and review articles are published on the occasions of the triennial International PIXE Conferences. Several reviews are available.

### 3.2 Biomedical Applications

Biomedical applications of PIXE have been reviewed in detail together with exhaustive lists of references. Also for biomedical work, a large number of specific papers are published in the Proceedings of the International PIXE Conferences, and the more recent topical series of bio-PIXE Conferences.

The main reason for the great success of PIXE in biomedical applications is linked to the very nature of biological materials, where light elements – undetected by PIXE – are the dominant component. This favors attaining the best results in terms of MDLs for higher-Z elements. Provided that the samples can tolerate the relatively intense beam currents, MDLs well below the ppm level are easily reached. This trace element capability makes it possible to obtain precious information on physiological and pathological processes in biomedicine, where the oligo-elements often play a key role. The problem is in the correct preparation of the samples, because the biological matrix is easily damaged by irradiation and elements such as hydrogen and oxygen may be lost to a large extent due to heating. However, when these problems are adequately tackled, biomedical applications of PIXE can yield important results.

The second feature of PIXE that is important in biomedical applications is the high spatial resolution, i.e. the possibility of mapping trace element distributions in the tissues with a high definition. If a microbeam is used, the intracellular distribution of trace elements may be revealed.

To obtain good results in biomedical PIXE applications, close interdisciplinary collaboration between physicists and biologists is important at all stages of the experiment. This includes experiment design, sample preparation, data collection and processing, and interpretation of the results.

Traditionally, applications of PIXE in biomedicine have focused on the detection of trace quantities of transition elements and heavier elements in tissues. More recently, interest has shifted to the detection of lighter elements, such as aluminum, potassium and calcium. Often, the low concentration levels of these elements, which are well within the analytical capabilities of PIXE, are not easy to detect with alternative techniques, especially when dealing with small tissue samples or at the cellular level.

The sampling strategy is crucial to obtaining significant biodata from any analytical technique and must be adapted to the specific features of the chosen methodology. An essential point to bear in mind is that a large number of samples is necessary because of the large variability of trace element concentrations in biological
tissues. In this respect, PIXE is a good choice because it can analyze large numbers of samples in a relatively short time, in addition to preserving them for further complementary analysis. The latter point is an advantage in biomedical investigations because the bio-availability of trace elements may be quite different, depending on the chemical form in which the elements are bound. Thus, further analysis of the same sample can be performed to yield this essential chemical bonding information.

Bio-PIXE experiments are usually performed on samples collected from living matter (biopsies). To avoid or minimize ethical problems connected with the acquiring of such samples, many investigations are performed on dermatological samples, such as nails or hair, as biological indicators of a physiological or pathological state of the individuals from which they were taken. The use of body fluids, such as sweat, tears, urine or blood, also implies minimum invasion in the sampling procedure. In any case, even when dealing with biopsies, the high absolute sensitivity of PIXE, requiring the collection of only minute amounts of tissue, is a good reason for selecting this technique. However, due to the very small amounts of sampled material involved, special care must be taken to avoid contamination from the surgical instruments used for the biopsies.

The need for small amounts of sampled material is beneficial to studies aimed at clarifying the processes of forest decline. Drill cores are collected from trees, small enough as not to harm them, and the radial trend of contaminant elements from environmental agents studied along the tree rings. One exploits here the fact that, in plants, only the external layer is living matter, interacting with the environment, and that each annual tree ring records the elemental content resulting from equilibrium with the environment for the corresponding year. Past environmental conditions can be thus reconstructed by simple PIXE scans on the small samples collected.

Sample preparation for bio-PIXE analysis depends on whether macro-analysis or micro-analysis is intended.

In macro-analysis, the desired spatial resolution in the detected elemental concentration is no smaller than a fraction of a millimeter; sometimes an average over a larger dimension is requested. When this is the case, many biological materials can be analyzed with a minimum of preparation, especially when an external beam set-up is used. Examples of materials analyzed in this way are botanical samples such as leaves, wood, and tree rings, or animal (or human) specimens such as bones, nails, hair, and teeth. Direct beam bombardment is possible in these cases, but no internal standard can be included and the absolute quantitative analysis may be difficult with PIXE alone because the matrix material is to a large extent undetected. However, in these studies it is often the relative behavior of minor or trace element concentrations that is searched for, so the matrix composition can be unimportant. Another point to be kept in mind when extracting analytical information from these untreated thick samples is that the total quantity of interrogated material volume is small, in the milligram range, due to the essentially surface character of PIXE analysis (section 2.2.2). Caution must be used in evaluating the representativeness of the results, which may be questioned if the material is not homogeneous to the macroscopic scale. Finally, surface roughness can also cause inaccuracies in the quantitative data, especially as far as lower-Z elements are concerned.

Soft tissues are often dried before analysis. The technique of lyophilization by freeze-drying is most common and performed by commercially available equipment. It has been shown that, for macro-analysis, the original composition is not affected by this procedure (whereas the spatial distribution of elements in micro-analysis could be affected if crystals are formed or thawing occurs). After drying, the tissues may be pulverized, homogenized and compressed to pellets for analysis. In this process, the material can be mixed with ultra-pure carbon powder, to ensure that the sample is electrically conductive. This avoids problems connected with insulated samples during bombardment. Throughout all these steps, great care must be taken to avoid contamination, such as from the pressing surfaces of the pelletizer.

To further increase sensitivity to the trace elements, the organic matrix mass can be reduced by well-established techniques such as wet ashing, dry ashing, low-temperature ashing, and acid digestion. The possible selective loss of some elements (e.g. chlorine and bromine in dry ashing) must be considered with care.

The preparation of biological samples for micro-PIXE analysis is different. It is clear that, for the result to be significant in terms of biological information about trace element distribution at the cellular or sub-cellular level, the spatial structure must be preserved during sample preparation and irradiation. Experience gained in the preparation of samples for electron microscopy is only of partial help here, because in those preparations chemicals are often added to increase visual contrast, and these may contaminate or selectively remove certain elements. Cryo-preparation techniques have been developed instead that lead to almost instantaneous freezing of the cells with preservation of a life-like state in terms of the elemental distribution. The frozen material must then be maintained at low temperature (below 130°C) and the analysis performed on thin sections obtained with an ultracryomicrotome. As these sections show very little image contrast in using optical microscopy, their positioning under the microbeam with traditional optical methods is difficult. Contrast enhancement by
3.3 Applications to Earth Science

Review treatments of PIXE applications in the earth sciences have been given in several articles. (See references 2 [Chapter 3], 45, 46)

The impact of PIXE for the earth sciences has increased during the 1990s, with developments in microbeam technology. Micro-PIXE has early been acknowledged by geologists as an ideal complement to traditional compositional investigations using EPMA. The very low MDLs attainable by PIXE, even on the micrometric scale, make it very attractive to extend to trace elements the studies of elemental partitioning between different phases in a rock, or the zoning effects within a single crystal.

Whereas the MDLs of EPMA can be pushed at most to hundreds of ppm, micro-PIXE with beams of the order of 10 µm can reach, with relative ease, a factor of more than 100-fold better, i.e., ppm sensitivity. The attraction for Earth scientists is that this extra sensitivity is achieved with the same sample preparation (thin sections glued on a glass support) and using the same analytical principle used for EPMA (i.e., X-ray spectroscopy), with which they are so familiar. In the preparation of thin sections for PIXE, it must be remembered that the penetration of 2–3 MeV protons is larger than for 20–30 keV electrons (section 1.3.1). Therefore, thicker sections must be cut (about 70–80 µm; the standard thickness for EPMA is 30 µm), to prevent the protons from reaching the backing. With this precaution, both techniques can be used on the very same sample. In addition to providing additional information on trace elements, PIXE also provides quantification of the major and minor elements so that the results can be compared to EPMA data for the latter elements. What is crucially important is that the additional trace-element analysis provided by PIXE is achieved in a nondestructive manner, unlike alternative highly sensitive techniques with high spatial resolution, such as mass spectrometries SIMS (secondary ion mass spectroscopy) or LAMS (laser ablation mass spectroscopy).

In comparing EMPA and PIXE results for major and minor elements, the differences in the probed depth and in spatial resolution (section 1.3.1) must be considered. This comparison is useful in that it adds reliability to the overall analytical data. The quantification of elemental concentrations from the PIXE spectra can be as accurate as 1–2%, for two reasons. First, the sample thickness is infinite and the problems connected with knowledge of the integration interval, discussed in section 2.2.2, are avoided. Second, the undetected fraction (very light elements) is in most cases (such as for silicate rocks) easy to estimate just on the basis of the detected fraction; or even all elements are actually detected, as in sulfide rocks. In silicate rocks the elements can be considered to be present in the form of oxides, thus the only undetected element is oxygen and its abundance can be estimated from the stoichiometric ratios to the detected elements. In practice, an initial estimate is done of the total oxygen abundance (which is often around 40%), in order to make a first approximation of the matrix effects in the computations described in section 2.2.2. Iterative procedures then lead to a self-consistent dataset of all elemental abundances, oxygen included.

Typical problems that have been addressed by micro-PIXE in the field of earth sciences are trace element partitioning between phases, which provides important clues to the physical and chemical parameters of the environment at the time of rock formation, and mineral zoning effects as regards trace elements. The latter frequently do not follow the pattern of major elements, and the different behavior is of relevance to geologists. These investigations require a beam of small dimensions; however, this does not necessarily imply the use of a microbeam. Beam sizes of a few tens of microns may often be adequate. One should keep in mind that the depth within the mineral, interrogated by the proton beam, is of the order of 10 µm, or more for the medium-to-heavy elements typically searched for in trace quantities. A higher lateral resolution would therefore bring no benefit (section 2.7). The relatively broad size of microbeam required means that no specially refined tuning is needed on the set-up.

More traditional, broader beam sizes have been used to investigate rocks to obtain bulk composition data. Here, the obvious competitor to PIXE is XRF which, when operating on a larger spatial scale, is capable of yielding trace element abundance. Indeed, the same kind of problems are addressed by XRF and PIXE, and even the same samples can be used. As the problem in bulk composition analysis is the inhomogeneous structure of the rocks, the latter have to be thoroughly ground to a very fine powder and homogenized. The final sample preparation step is usually pressing the material into pellets, which are then exposed to the X-ray or proton beam. Due to the trace element capability of both techniques, great care must be taken to avoid contamination by the instruments used for grinding and pressing. Although in principle both XRF and PIXE are capable of yielding global information on composition, it must be said that the former technique has better MDLs, if properly applied, for the higher-Z elements, whereas PIXE is better for the lighter ones. Another difference lies in the different depth investigated, but
this is not relevant for homogenized samples because the pellets are effectively infinitely thick for both techniques. Finally, a common feature of XRF and PIXE analyses, which is disappointing to geologists, is that the important problem of rare earth patterns cannot be investigated. On the one hand, the detection efficiency for the K-lines of rare earth elements (which are sufficiently energy separated from each other) is too low, so that they cannot be detected at their low levels of concentrations. On the other hand, the L-series X-rays, which might instead be detected with more efficiency, cannot be safely deconvoluted because the overlaps of their multiplets are too close. Some work has been done to overcome these problems. Higher-energy PIXE has been attempted, but the advantage of the increase in K-series X-ray production cross-sections is accompanied by a much higher continuous background, induced in the spectra by the onset of many nuclear reactions. The latter lead to emission of gamma rays, producing Compton interactions in the detector (section 3.1). Also the attempt for a proper deconvolution of the close-lying multiplets of L-series X-rays was basically unsuccessful, as even small differences in the assumed X-ray lineshape in the spectrum fitting procedure alter the deduced relative intensities of the various elements.

When considering broad-beam PIXE applications in the earth sciences, not only XRF but all the other traditional techniques can usually be applied as well. This is because there is usually plenty of material to analyze and the nondestructive character of XRF and PIXE becomes less important. The advantage of XRF and PIXE is in their multi-element capability, which makes the compositional characterization of samples from bulk materials much faster. However, as a summary consideration one should admit that the real benefit of PIXE to the earth sciences is only when using microbeams for trace-element distribution studies.

3.4 Applications to Art and Archaeology

Recent surveys of PIXE applications in the field of art and archaeology can be found.\(^{(47,48)}\) These applications probably started later than those mentioned above, but have now been developed to a large extent as a result of more widespread use of external beam set-ups. The importance of PIXE measurements (and IBA in general) in this domain is demonstrated by the installation of a dedicated accelerator in the Laboratoire de Recherche des Musées de France, in the basements of the buildings of the Louvre Museum in Paris.\(^{(49−51)}\) With the prominent use of PIXE analyses among others, this accelerator has produced significant contributions to a better understanding of the materials and techniques used in the past for the production of works of art. Intense and significant activity in this field has also been performed in many other laboratories throughout the world.

The problems addressed by PIXE analysis in this field fall into two categories: first, an advancement of the knowledge of materials and production technologies used in works of art in ancient times; second, the investigation of materials prior to restorations, so as to appropriately choose the restoring procedure, and avoid incompatibilities and irreversible effects between materials.

The motivating forces within the first category can be many. Reconstructing the material composition of artifacts may lead to:

- deeper insight into the technical developments of the past, allowing the historian to better understand the advance in the technological skills of artisans at various sites and times;
- discovery of the sources of supply of raw materials, thus contributing to the solution of historical problems, such as the existence of certain trade routes at the time of manufacture of the ancient objects under analysis;
- indirect dating through compositional analogies with dated materials and, under favorable circumstances, lending support to attributions to specific artists, providing a criterion for authentication (or refutation).

To the second category of problems, namely the restoration of works, should be added the significant contribution to a better understanding of the deterioration of the works of art.

Whatever the reason for analyzing the material of an object of artistic or archaeological relevance, in almost all cases a mandatory requirement is that no damage must occur, and quite often the physical removal of some material for analysis is forbidden. This raises a difficulty in that the inherent inhomogeneity of the materials used to produce works of art (whether one is dealing with paints, or metal alloys, or terracotta, or any other) calls for an analysis extended to many samples. The representativeness of the results might be otherwise questioned. Hence there is a need to perform such analyses with techniques capable of yielding a full compositional characterization of artifacts in a fast and nondestructive way. PIXE meets these requirements probably better than any other analytical technique. With the exception of metal objects, external set-ups are needed so that the nondamaging character of the technique is thus fully preserved provided that sufficiently low beam currents are used. Low beam intensities, on the other hand, are feasible in most investigations because of the nonthin targets (i.e. the quantity of material is relatively large) and because the problem is often not the
search for trace elements. Typical beam currents used in this kind of application are well below 1 nA, sometimes down to a few picoamps.

In terms of risks of damage, the most sensitive precious materials are glass, porcelains, and any vitrified surface. With these materials, even with external beams, currents of a few tens of picoamps can sometimes produce a visible stain after a measurement. This sort of damage can often be tolerated, but the curator of the object must be warned about the risk. This damage is attributed to atomic dislocations in the structure of the material, giving rise to color centres. Stains induced in this manner have been often reported to fade away after some days or weeks, due to a self-annealing process, even at room temperature. To minimize the effect, whenever the sample size makes it possible, a diffused beam over a larger area may be employed, or a smaller-size beam may be scanned across the surface (or the surface moved under the beam).

Although all kinds of materials may be analyzed by PIXE, most published work has concentrated on gold artifacts (coins, jewels), temperas used in miniatures in illuminated manuscripts or incunabula, and terracotta. Relatively little PIXE activity has concerned the materials of traditional paint on wood or canvas. This is because PIXE is a surface analysis technique, and little or nothing can be discovered about the deeper layers. Thus, if PIXE is performed on the paintings as they are, the protective varnish, which is invariably laid over the color in paintings on wood or canvas, prevents access to the paint materials. Material sampling is seldom allowed; alternatively, the varnish could be removed, but this is only done on the occasion of restorations, and is not normally permitted for general investigations, such as when trying to characterize the color palette of a given painter or school.

For paints, the field where PIXE is best exploited is that of illuminated ancient books. Here, no varnish was used because the paints were believed to be naturally protected by remaining unexposed to direct light and atmospheric agents for most of the time. Much PIXE work has concentrated on this subject, and unexpected results of art-historical importance have been found; for instance, the widespread use of ultramarine blue has been detected in Italian scriptoria dating from early medieval times. Until this finding it was believed that this pigment (obtained by a sophisticated refining technique from lapislazuli, a semiprecious stone only found in Afghanistan) was reserved for very important works, at least until the early Renaissance, because of the high cost of import from a distant site.

All PIXE work on miniature paints has been performed with external beam set-ups. This is essential with manuscripts, because of handling considerations and because only by the use of an external beam (in a helium flow) can the measurements be really nondamaging, in all senses.

The surface character of PIXE analysis also explains why most of the published work on metal products concerns gold. The surface patina layer covering ancient objects made of other metals is a problem to PIXE, unless the material under study is the patina itself (which can in fact be the case sometimes). As far as gold items are important work includes that by Demortier, which led among other things to the discovery of skilful soldering techniques as early as 3000 years ago. This work demonstrated the use of various gold alloys with decreasing melting temperatures, which avoided the unsoldering of nearby previously soldered details. These measurements have been performed both with external beams and with in-vacuum microbeams. For this kind of object, indeed, no disadvantage (damage, or difficult handling due to large size) comes from the use of a vacuum set-up, whereas the use of an in-vacuum microbeam provides sometimes a better tool of analysis.

Terracotta has been often investigated by PIXE analysis. The information searched for in this case is usually a provenance clue, often based on the trace-element content of the material. Thus, the PIXE quality most exploited is its very low MDLs. When dealing with terracotta, the compositional analysis is usually performed on fragments, whose esthetical value is irrelevant; therefore, higher beam currents may be used with no fear of possible visible damage, and the sensitivity to trace elements achieved in runs lasting a few minutes. However, due to the surface character of PIXE analysis, caution must be exercised when deriving conclusions from the detection of traces—surface contamination might be the reason for finding trace concentrations of unexpected elements. These risks must be carefully evaluated and procedures for reducing them adopted (such as analysis of cleaved surfaces of the fragments, or preliminary cleaning with appropriate noncontaminant processes). The statistical analysis of detected trace-element abundances over large series of samples may also help in discriminating significant results from accidental findings. An alternative to direct irradiation is to sample some material, which in small amounts is often allowed when dealing with fragments. In these cases, the material can be powdered and pressed into pellets for analysis. The same considerations as for the analysis of rocks with macro-PIXE (section 3.3) apply in this respect, in particular about the alternatives to PIXE for these analyses.

An example of extensive PIXE investigations of this kind is the analysis of pottery and obsidian artifacts performed in Australia. A large number of pottery samples have been analyzed with a PIXE/PIGE set-up; their composition was clearly correlated to local
sources of clay, which made it possible to establish relationships between prehistoric settlements and their trade connections. The obsidian artifacts, which were largely used by prehistoric populations as tools for everyday life or for hunting, were prepared using material collected from local deposits of volcanic origin. The compositional characterization of hundreds of these tools by PIXE and PIGE, followed by statistical analysis for pattern recognition, made clear separations into different groups possible. Because the populations took their tools with them when migrating from one land to another (even over distances of thousands of kilometers), the archaeologists were able to reconstruct the processes of migration by matching the composition of obsidian tools to that of volcanic flows in quite different places.

3.5 Applications to Historical Problems

Although related to the previous section, the studies described below have been separated out because, for them, the use of PIXE has been particularly useful and in certain respects unique. The study of ancient written documents, namely of the composition of paper, parchment, and especially ink, is a tool to characterize and differentiate them. Such characterizations address problems of chronology, authenticity, or technical procedures for the production of books in ancient times. For the study of inks in particular, PIXE is an exceptionally suited tool owing to its high absolute sensitivity, its nondestructivity, the possibility of using beams well below 1 mm in diameter in external set-ups and to perform simultaneous quantitative analysis of many elements. All these features make it really useful for these problems.

In a study of one exemplar of the Gutenberg Bible, the paper and ink were analyzed by an external 1-mm² beam. The ink was notable for its high Cu and Pb content, and their weight ratio was used to characterize the ink. It was thus possible to reconstruct the sequence of printing of the various pages of the book.

Another study of the same group concerned the so-called Vinland map, which is believed to be a pre-Columbus document giving the first cartographic evidence of North America. However, its authenticity had been debated and after a chemical analysis (which was performed on a forcibly limited number of tiny samples of ink, as they had to be picked up from the map), it was concluded that it must be a forgery because of a high content of TiO₂, which has become available only in recent times. An extensive PIXE analysis of ink from this document, performed instead on a very large number of spots, with no need for picking up material and no damage, showed that the amount of titanium was in fact quite small, thus re-opening the possibility that the map is authentic. In this case, the nondestructive character of a PIXE analysis in situ was the winning card.

Ink analysis by PIXE has also been used to indirectly reconstruct the chronology of documents, as in the following example. During his life Galileo produced, besides the published works, hundreds of notes, handwritten on loose sheets of paper, where he wrote propositions and sketched diagrams about his ideas on the problems of motion and on astronomy. These sheets are obviously undated and conflicting opinions have been raised within the community of science historians about their chronological order. Establishing their dates on the basis of an objective criterion is important for the reconstruction of the development of Galilean thought. Analysis with PIXE of the ink composition in some of Galileo’s dated hand-written documents – such as letters – first showed that a correlation can be established between different ink compositions and periods of Galileo’s life. The inks are of the so-called metallo-gallic type and the quantitative ratios between the various metallic components (Fe, Ni, Cu, Zn, Pb) vary from one manuscript to another, so that they can be used to characterize different periods. The idea is then to characterize the ink of the undated propositions in the loose sheets, and attribute them to the different periods on the basis of composition matches to the dated documents. Even when an absolute date cannot be established, an important objective is a relative dating, i.e. differentiation between the inks of the various undated documents. Indeed, most of the controversies concerned whether certain notes had been written at the same or at different times. Using these criteria, both absolute and relative dating have been possible for a number of these loose sheets and controversies between historians of science have been solved. It is important to keep in mind that this contribution is to be considered in the frame of a global approach where the historical and textual evidence is of course of primary importance. This calls for the need for integrated teams of researchers from the various fields to work together throughout all the phases of the investigation.

From a technical point of view, PIXE analysis of the inks in documents is easily performed with external beams. The typical beam size used is between 200µm and 1 mm, with no need for microbeam set-ups. Because the elements of interest are not trace elements in the inks, but are major or minor components, the beam currents may be kept very low (typically 100–200 pA) and no damage occurs. In extracting quantitative data, two circumstances must be considered. First, the beam will also excite X-rays from the paper (or parchment) substrate, so that the result refers to an effective target that is a combination of ink and substrate. This is taken into account by measurements on spots of uncovered substrate, and appropriate subtraction of the backing contribution, after beam charge normalization of the
ink plus substrate and substrate-only spectra. Second, the ink actually penetrates the substrate, to an extent depending on many factors such as substrate porosity, ink fluidity at the very instant of writing, and even ageing phenomena. These effects can lead to ambiguities in that the target thickness and the matrix composition of the effective target are to some extent uncertain. However, as far as the ratio of the elements of interest (medium or heavy metals) is concerned, it can be shown that the value deduced with no matrix correction is only weakly dependent on these parameters. Therefore, the accuracy of the thin target approximation (sections 2.2.1 and 2.2.2) remains sufficient for a meaningful ink discrimination (about 10% for the measured ratios). The differences between different inks are much larger than that, even with changes of orders of magnitude having been observed.

Prompt $\gamma$-Neutron Activation Analysis

Carlos Oliveira, José Salgado, and Frederico G. Carvalho
ITN-Nuclear and Technological Institute, Sacavém, Portugal

1 Introduction

PGNAA is a powerful analytical technique that can provide accurate information on the elemental composition of materials in a broad range of cases: raw materials, mineral exploration, contaminants, detection of forbidden products, such as drugs and explosives, inspection of containers and applications in health care.

When a material is bombarded with neutrons, nuclear interactions in the sample may lead to the formation of excited compound nuclei that lose their excitation energy by the emission of one or more $\gamma$-rays (prompt $\gamma$-rays) and eventually one or more particles. PGNAA is based on the detection of the emitted $\gamma$-rays. The $\gamma$-ray energy identifies the element while the intensity of the line is a measure of the element concentration.

The analysis is the result of a combination of a number of different processes or steps:

- neutron emission by a neutron source (radioisotope, neutron generator, nuclear reactor, spallation source);
- neutron interaction with the sample's constituent nuclei;
- emission of $\gamma$-rays following neutron capture or neutron inelastic scattering;
- $\gamma$-ray attenuation in the material;

1 INTRODUCTION

PGNAA is a powerful analytical technique that can provide accurate information on the elemental composition of materials in a broad range of cases: raw materials, mineral exploration, contaminants, detection of forbidden products, such as drugs and explosives, inspection of containers and applications in health care.

When a material is bombarded with neutrons, nuclear interactions in the sample may lead to the formation of excited compound nuclei that lose their excitation energy by the emission of one or more $\gamma$-rays (prompt $\gamma$-rays) and eventually one or more particles. PGNAA is based on the detection of the emitted $\gamma$-rays. The $\gamma$-ray energy identifies the element while the intensity of the line is a measure of the element concentration.

The analysis is the result of a combination of a number of different processes or steps:

- neutron emission by a neutron source (radioisotope, neutron generator, nuclear reactor, spallation source);
- neutron interaction with the sample's constituent nuclei;
- emission of $\gamma$-rays following neutron capture or neutron inelastic scattering;
- $\gamma$-ray attenuation in the material;
• detection of γ-rays (solid state or scintillation detector);
• conversion of detector counts in percent weight for the elements being analyzed based on a previous calibration of the system.

These steps and processes will be addressed in the following sections.

The PGNAA technique is best suited for measuring elements: (1) with very high neutron capture cross-section; (2) elements that decay too rapidly to be measured by conventional DGNAA; and (3) elements that through neutron reactions generate only stable isotopes or radioactive isotopes with a low probability of γ-decay.

The main advantages of PGNAA are: faster results; nondestructiveness (sample preparation is not needed); flexible sample requirements; bulk sample analysis (representative average for nonhomogeneous materials); in situ application by direct on-line measurement; detectable unique signatures for most elements; improved accuracy for short-lived elements; low residual sample activity.

On the other hand, the most significant handicaps are: higher DLs as compared with DGNAA, which restricts the number of elements that can be measured at trace concentrations; longer irradiation times; single (one-cycle) sample irradiation; impracticability of radio-chemical or physical (half-life) separation to enhance specific isotope contributions; requirement for relatively larger samples.

The gauge response of a PGNAA analyzer is determined in a complex manner by the system parameters – geometry, source activity and neutron energy spectrum, and detector efficiency – and by certain properties of the analyzed sample such as bulk density and water content. It follows that the count rate caused by a given γ-ray line is a nonlinear function of the concentration of the element to be measured. There are, in principle, several methods for calibrating a PGNAA gauge. Experimental calibration methods use standards of known composition. An alternative method is the use of Monte Carlo codes to simulate the sample spectra and/or to establish calibration curves.

Trends in the evolution of PGNAA relate to both the instruments of the technique and the range of its applications.

The use of advanced neutron sources, improved spectrometers (Compton suppression and pair spectrometer), nuclear imaging techniques, sophisticated calibration methods and the extension of PGNAA to new materials and sample types are some of the trends which indicate that this technique has a promising future.

2 THEORY AND APPLICABILITY OF THE METHOD

Neutrons are electrically neutral; they are not affected by atomic electrons or by the positive charge of the nucleus. Neutrons can pass through the atomic cloud and interact directly with the nucleus; they are highly penetrating in most materials. On the other hand, the attenuation coefficient of γ-rays for most elements decreases monotonically with energy in the range from 0.1 to 10 MeV so that γ-rays with energy > 2 MeV are also relatively penetrating. Thus neutron–gamma based techniques do not suffer from the limitations of penetration of X-rays and β-rays and are favored for investigating bulky materials. Sample preparation is not required. All the major elements can be assayed provided a high-resolution detector is used.

Neutron activation analysis (NAA) is an important elemental analytical technique with many applications in different fields: industry, medicine, resource exploration, forensic work, and so on.

2.1 Physical Principles

When a material is bombarded with neutrons, a neutron can be captured by a nucleus, forming a compound nucleus. The compound nucleus remains for a certain time in a highly excited state due to the addition of the binding energy of the neutron to the nucleus. It will lose this energy by the emission of one or more γ-rays (prompt γ-rays) and eventually one or more particles.

![Figure 1](image-url)
namely one neutron (inelastic scattering), which can be accompanied by several γ-rays. After the emission of this primary radiation, the daughter nucleus can remain unstable (radioactive), decaying to the ground state by a β-decay process, followed by γ-emission (delayed γ-rays).

As shown in Figure 1, the de-excitation of the compound nucleus may take the form of a stepwise process, which can be very complex, originating a spectrum with a large number of lines (89 for Si, 449 for Cl, 113 for Ca and 187 for Fe). Most of these lines have a very small relative intensity. The large number of emitted photons is due to (1) the high binding energy of the compound nucleus and (2) the narrowing of the energy gap between levels with increasing excitation energy. Two other causes of the increase in the number of lines in a spectrum must also be taken into account: (1) every isotope has its own decay scheme and (2) the high-energy γ-photons may interact through pair production in the detector. The subsequent positron annihilation originates the emission of two 0.511 MeV γ-rays. One or both of these γ-rays may escape the detector. This means that every γ-line may be split in three lines (the full \( E_\gamma \); the single escape \( s \), with energy \( E_\gamma - 0.511 \) MeV; and the double escape \( d \), with energy \( E_\gamma - 1.022 \) MeV. The γ-ray spectrum is a signature of the sample elemental composition. The intensity of the lines is proportional to the weight content of the respective element.

Prompt γ-rays are emitted within \( 10^{-15} - 10^{-14} \) s of the interaction; delayed γ-rays originate in the decay of induced radioactivity. Two types of activation analysis can, then, be used: PGNAA when information is derived from prompt γ-rays and conventional instrumental neutron activation analysis (INAA) or DGNAA, where information is derived from delayed γ-rays (Figure 2).

In the second case, the irradiated samples are normally removed from the irradiation position to detect the delayed γ-rays.

PGNAA is based on the analysis of a few γ-lines for each element. The selection of these lines takes into account their intensity and interference from other lines.

Two physical mechanisms predominate in PGNAA: thermal neutron capture reactions \( (n, \gamma) \) and fast neutron inelastic scattering \( (n, n' \gamma) \).

**Thermal neutron capture**

\[
2X(n, \gamma)_Z^{A+1}X^* \rightarrow ^{27}_{13}\text{Al} (n, \gamma)^{28}_{13}\text{Al}
\]

\( E_\gamma = 7.724 \) MeV

**Fast neutron inelastic scattering**

\[
(n, n' \gamma)
\]
Inelastic scattering \( \frac{1}{2}X(n, n')\frac{1}{2}X \)\(^{208}\)Pb\((n, n')\)\(^{208}\)Pb \( E_r = 2.615 \) MeV

For every nucleus there is a definite probability (cross-section) of thermal neutron capture \( (\sigma_{1\text{th}}) \) and/or inelastic scattering \( (\sigma_{14\text{MeV}}) \), as shown in Table 1.

The larger the cross-section the larger the number of reactions the information derived from the detector count rate originates in thermal neutron reactions (thermal component of the neutron flux). For most elements the thermal component can be approximated by a Maxwell distribution and this will be indicated in the following formula by substituting M for \( \Phi_{1\text{th}}(E_n) \).

Equation (1) can thus be rewritten as Equation (3):

\[
R_{ij} = \frac{N_A w_j \theta I_{ij} e_i}{4\pi M_j} \Phi(E_{th}, r) \frac{\Phi(E_n, r) \sigma_j(E_n)}{E_n} \int_{R_d} \Phi(E_n, r) dE_n dV
\]

where \( N_A \) is the Avogadro number; \( w_j \), the weight content of element \( j \); \( M_j \), the atomic mass; \( \rho \), the bulk density \( (\rho = w_j \times \rho) \) is the mass of element \( j \); \( I_{ij} \), the number of photons pertaining to element \( j \), with energy \( E_i \), emitted per neutron captured; \( e_i \), the detector efficiency for photons of energy \( E_i \); \( \Phi(E_n, r) \), the energy-dependent neutron flux, at position \( r \); \( \sigma_j(E_n) \), the average element microscopic cross-section for the nuclear reaction that originates the \( \gamma \)-line of interest; \( R_d \), the path in the medium along the line drawn through volume element \( dV \) and the detection position; \( \mu(E_i) \), the mass attenuation coefficient; and \( S \), the detector surface.

When the energy dependence of the neutron flux inside the medium does not vary with position, the flux dependence on \( E_n \) and \( r \) can be separated. This happens, for instance, throughout the volume of a moderating material such as coal\(^{2,3} \) when using \(^{241}\)Am-Be, \(^{225}\)Cf or 14 MeV neutron sources. Also the thermal and fast neutron fluxes can be formally separated and the neutron flux can be written as Equation (2):

\[
\Phi(E_n, r) = \Phi_{1\text{th}}(E_n) \Phi_{1\text{th}}(r) + \Phi_{14\text{MeV}}(E_n) \Phi_{14\text{MeV}}(r)
\]

where \( \Phi_{1\text{th}} \) and \( \Phi_{14\text{MeV}} \) refer, respectively, to the thermal and the fast neutron fluxes. The energy dependence of the thermal component can be approximated by a Maxwell distribution and this will be indicated in the following formula by substituting M for \( \Phi_{1\text{th}}(E_n) \).

Equation (1) can thus be rewritten as Equation (3):

\[
R_{ij}^{\text{c}} = \frac{N_A m_j}{4\pi M_j} I_{ij} e_i \Phi_{1\text{th}}(E_n) \Phi_{1\text{th}}(r) \int_{R_d} \Phi(E_n, r) dE_n dV
\]

where the superscripts \( I \) and \( C \) refer to \( (n, n') \) and \( (n, \gamma) \) reactions, respectively. Equation (3) gives the count rate, \( R_{ij}^{\text{c}} \), arising from the fast component of the neutron flux or gives the count rate, \( R_{ij}^{\text{C}} \), coming from the thermal component of the neutron flux. For most elements the thermal neutron capture predominates. In fact, in most applications the information derived from the detector count rate originates in thermal neutron reactions (thermal PGNA); in certain special cases, however, fast neutrons are used to obtain information on the sample composition (fast PGNA). Taking into account that the Maxwellian distribution has the expression in Equation (4):

\[
\Phi_{\text{M}}(E_n) = \frac{1}{(kT)^2} E \exp \left( -\frac{E}{kT} \right)
\]

where \( k \) is the Boltzmann constant and \( T \) the neutron temperature, Equation (3) takes the form, Equation (5):

\[
R_{ij}^{\text{c}} = \frac{N_A m_j}{4\pi M_j} I_{ij} e_i \Phi_{1\text{th}}(E_n) \int_{R_d} \Phi(E_n, r) dE_n dV
\]

where \( \sigma_{i0} \) is the element averaged 2200 m s\(^{-1} \) neutron capture cross-section.

This equation shows that the count rate from a given line is proportional to the sample content of element \( j \). However when a perturbation of the fast neutron flux is
caused by the sample, as happens currently in applications using isotopic neutron sources and large samples, the volume integral depends on the sample bulk density and composition, particularly on the water content. Fast neutrons emitted by the neutron source are generally moderated inside the sample. An increase of the bulk density and/or of the water content (or hydrogen content), will increase the thermal neutron flux and, consequently, the reaction rate. On the other hand, increasing the bulk density will increase the attenuation of photons inside the sample. The two effects have, thus, opposite signs and can cancel each other. An optimized design of the measuring arrangement (geometry, proper choice of sample size, amount of external thermalization) can make the volume integral essentially independent of sample density and composition.

In certain cases it is important to take into account the contribution of the epithermal neutrons to the detector count rate. To this end the thermal neutron cross-section can be substituted by the quantity shown in Equation (6):

$$g \sigma_{l,0} + I_0 \frac{\Phi_{epi}}{\Phi_{th}}$$  \hspace{1cm} (6)

where $\Phi_{epi}$ is the epithermal flux, $g$ is the Wescott constant and $I_0$ the resonance integral, Equation (7):

$$I_0 = \int_{E_{th}}^{\infty} \sigma(E) \frac{dE}{E}$$  \hspace{1cm} (7)

2.2 Detectability and Sensitivity

In Equation (5) the quantity $S_l = \lambda/\sigma M$ is constant for a given $\gamma$-ray pertaining to a given element. $S_l$ is called sensitivity factor or index and is a useful measure of the relative sensitivity of the method for different elements under the same experimental conditions. Table 2 shows selected sensitivity factors of different elements when using gamma energies above 2.223 MeV.

Examination of the data shows that certain elements can be very easily detected by PGNAA. These include H, B, C, N, Na, Al, Cl, Ca, Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, Dy, Au and Hg.

For thermal PGNAA to be appropriate for the detection of an element it is not sufficient that the element has a high sensitivity factor. It is important that the useful gamma lines of the element show a high spectral contrast.

$^a$ In the case of B, the sensitivity can be enhanced (approx. 73) if the 0.48 MeV $\gamma$-ray from the reaction $^{10}$B(n,a) is detected. This is usually only done when the low energy gamma background does not disturb the measurement.
The sensitivity factor gives qualitative information only: elements with high sensitivity factors will be more easily detected in a complex matrix. However, it is necessary to quantify the feasibility of measuring an element. Two quantities are normally considered: the absolute sensitivity (in counts s\(^{-1}\) mg\(^{-1}\)) and the DL (in \(\mu g\) g\(^{-1}\)).

The DL is related to the absolute sensitivity, \(S\), through Equation (8):

\[
DL = 3.29 \frac{\sqrt{R_b/t}}{S}
\]  

(8)

where \(R_b\) is the background count rate and \(t\) is the counting time.

Actual values of DL (or \(S\)) for a given arrangement and element are determined experimentally.

The two quantities, \(S\) and DL, depend on intrinsic sample characteristics related to nuclear properties of the elements (cross-section; number of \(\gamma\)-rays emitted and atomic mass; matrix interferences) and on parameters of the measuring arrangement (neutron spectrum and flux, sample dimensions, detector efficiency and resolution, background). For example, a reactor-based facility using a cold neutron source, guide tubes and a high-resolution germanium detector with Compton suppression, will normally show higher absolute sensitivity (lower DLs) than an arrangement using an isotopic neutron source for on-line measurement of large samples conveyed on a belt.

The actual DLs vary from one arrangement to another, depending on the neutron flux in the sample, the distance between sample and detector and the background due to shielding. The DL of an element can be affected by interferences from other elements present in the sample or in shielding or structural materials.

The elemental DLs for reactor-based PGNAA facilities are usually much lower than those of facilities with isotopic sources, used in on-line measurements.

As an example, Table 3 shows the DLs of the PGNAA facility installed at the Cold Neutron Research Facility of the National Institute of Standards and Technology (NIST).\(^{5}\)

### 2.3 Prompt Versus Delayed Neutron Activation Analysis

As a laboratory analytical technique for routine sample analysis, PGNAA is generally complementary to the conventional delayed NAA systems installed at most research reactors. In contrast to DGNAA, the method is in principle applicable to all elements. As irradiation and measurement are carried out simultaneously, true multielement analysis is possible in a single measurement, at the expense of extremely complex \(\gamma\)-ray spectra.

DGNAA however is used intensively and is preferred for the determination of a large number of elements where no restrictions apply to handling and preparation of the sample. This is so because of the possibility of using higher neutron fluxes and of postirradiation counting that allow for background reduction and lower DLs.

In PGNAA arrangements installed at reactor facilities a wide variety of samples, e.g. liquids, solids, gases, museum objects, hazardous materials, can be irradiated using extracted beams that have fewer limitations on sample size and composition. In all cases neutron fluxes used in PGNAA are currently one or more orders of magnitude lower than those used in DGNAA.

The PGNAA technique is best suited for measuring elements: (1) with extremely high neutron capture cross-section; (2) elements which decay too rapidly to be measured by DGNAA; and (3) elements which produce only stable isotopes or radioactive isotopes with low gamma decay probability.

Sample preparation is not needed for PGNAA, and the results are obtained immediately. The irradiated samples may be large, which is advantageous when a representative average for nonhomogeneous material is needed. (The accuracy of the results may be affected by the presence of inhomogeneities that influence significantly the neutron flux distribution in the sample bulk and/or the position-dependent gamma attenuation.) However, large-sized samples may lead to problems due to neutron self-shielding, and specially due to neutron scattering, particularly in hydrogen.

The main advantages of the PGNAA technique are summarized in Table 4. Foremost among the advantages are nondestructiveness and the fact that nearly all elements yield a detectable signal. On the other hand, the most significant handicap is higher DLs, which restricts the number of elements that can be measured at trace concentrations and the long irradiation times often required.

While comparing different NAA techniques mention should be made of pulsed NAA, a technique that borrows some features from both PGNAA and for DGNAA. Pulsed neutron sources, e.g. neutron generators, are used so that between pulses the delayed gamma emission from the sample can be detected separately from the prompt gammas. This approach can lead to enhanced signal-to-background ratios in specific situations.

3 EQUIPMENT

3.1 General

According to the physical principle of PGNAA an operational arrangement must include a neutron source, a detection system with appropriate electronics and adequate shielding for radiological safety purposes. Generally, a dedicated computer forms the interface between the equipment and the user.

The specific objective for which the PGNAA device is designed (nature of the samples, elements to be measured, type of nuclear reactions, expected \( \gamma \)-ray spectrum) determines the type of source, the detector and the electronics as well as the manner in which they are assembled. An arrangement for on-line control of an industrial process in a factory or an analyzer installed at the end of a neutron guide tube have quite different designs.

3.2 Neutron Sources

The choice of the neutron source is determined not only by requirements concerning nuclear parameters such as neutron energy and flux, and half-life (when an isotopic source is considered), but also by the specific conditions regarding its utilization. Different kinds of sources are available: isotopic sources, neutron generators, nuclear reactors and spallation sources.

3.2.1 Isotopic Neutron Sources

There are two types of isotopic neutron source used in PGNAA: \((\alpha,n)\) sources and fission sources.

Sources of the first type are based in \((\alpha,n)\) reactions of isotopes that have large cross-sections for neutron production. Beryllium is an outstanding example. The sources consist of a mixture of beryllium and an \(\alpha\)-emitter such as polonium or americium, the whole contained in a sealed capsule:

\[
^4_2\text{He} + ^9_4\text{Be} \longrightarrow ^{14}_6\text{N} + ^{12}_6\text{C}
\]

However, only a small number of \(\alpha\)-particles (1 in 10⁴) is effective in the production of neutrons so that the yield of the sources is relatively small. Also a background of \(\gamma\)-rays is present that is inconvenient for the application of the technique. Table 5 shows the main characteristics of several beryllium \((\alpha,n)\) sources.

Taking into account the neutron yield, the half-life of the \(\alpha\)-emitter and the \(\gamma\)-background, the \(^{241}\text{Am}\) isotope is currently preferred. There are \(^{241}\text{Am}\)-Be sources commercially available up to 925 GBq.

</table>
Spontaneous fission sources can be found in the region of the transuranium elements where the α-decay instability competes with spontaneous fission. However the half-lives of the transuranium elements are generally very short. The only nuclide with an acceptable half-life for use in applications is $^{252}$Cf ($T_{1/2} = 2.645$ y). This nuclide decays by α emission in 97% of the cases and by spontaneous fission in the remaining 3%. The average number of neutrons emitted per fission is 3.76. A source containing $3 \times 10^{10}$ Bq of $^{252}$Cf has a neutron yield of $4.3 \times 10^9$ n s$^{-1}$, which is three orders of magnitude higher than that of the more interesting ($\alpha$,n) sources. The γ-dose at 1 m from a source emitting $10^9$ n s$^{-1}$ is 0.0007 mGy h$^{-1}$ (a factor of 10 smaller than for a $^{241}$Am-Be source). The average neutron energy of a $^{252}$Cf source is 2.3 MeV.

In Figure 3 neutron spectra and γ-spectra for Cf and Am-Be sources are plotted for comparison.$^{(7)}$

The high specific activity of the Cf source is an advantage over the ($\alpha$,n) sources. Other advantages are small size and low heat and gas generation, which decreases the risk of source damage for long-term operation.$^{(8)}$ These radioisotope sources are used in PGNAA devices designed for field work.

### 3.2.2 Neutron Generators

Sealed tube neutron generators$^{(9,10)}$ are based on the following reactions:

\[
\begin{align*}
\text{H} -\text{H} & \rightarrow \text{He}(3.6 \text{ MeV}) + \text{n}(14.1 \text{ MeV}) \\
\text{H} -\text{H} & \rightarrow \text{He}(0.8 \text{ MeV}) + \text{n}(2.45 \text{ MeV})
\end{align*}
\]

In generators emitting 14.1-MeV neutrons, a deuterium ion beam (or a mixture of deuterium and tritium ions) is accelerated up to between 70 and 300 kV and made to impinge on a tritiated target (or a deuterated and tritiated target). In the latter case 2.45-MeV neutrons are also produced. However, the emission of 14.1-MeV neutrons dominates. It is possible to obtain an emission rate of $10^{11}$ n s$^{-1}$.

Tubes emitting 2.45-MeV neutrons are based on deuterium–deuterium reactions, i.e. a beam of deuterium ions is accelerated up to a few hundred kilovolts and impinges on a deuterium target. Neutron emission of such tubes may reach $10^{10}$ n s$^{-1}$.

A great advantage of neutron generator tubes is the possibility of on/off switching, i.e. the production of neutrons is stopped whenever required. Another interesting characteristic is the possibility of pulsing the neutron beam.

The lifetime of a sealed tube is limited by target heating and target sputtering from ion beam impurities.

A new neutron generator source has been presented: the inertial electrostatic confinement (IEC) device. The IEC device is a neutron source where deuteron ions are accelerated producing fusion reactions as they react with a deuterium plasma target. Commercially available units deliver $10^7$ of 2.45-MeV n s$^{-1}$ during steady-state operation. The neutron emission is isotropic. It is a practical low-to-medium-yield source for laboratory and industrial applications.$^{(11)}$

### 3.2.3 Nuclear Reactors

Nuclear reactors are still the most important neutron sources. The thermal neutron flux of a reactor source...
is of the order of $10^{13} \text{n cm}^{-2} \text{s}^{-1}$ up to $10^{15} \text{n cm}^{-2} \text{s}^{-1}$. The neutron energy spectrum can be divided into three components: fast, epithermal and thermal. Their relative importance is dependent on the reactor structure. Usually, the thermal neutrons constitute the most intense fraction. Thermal neutrons are in thermal equilibrium with the atoms of the reactor moderator; their most probable energy equals $kT$ (where $k$ is Boltzmann’s constant and $T$ is the neutron temperature). At room temperature the most probable energy is 0.025 eV. Epithermal neutrons have energies from $5kT$ to 0.8 MeV. Fast neutrons have energies $>\text{0.8 MeV}$.

PGNAA facilities are usually installed at the extraction end of a neutron beam tube (sometimes using a neutron guide). The performance can be enhanced by using subthermal or “cold” neutrons. These neutrons have energies lower than 10 meV. Cold neutrons are extracted from a cooled moderator placed in the neighborhood of the reactor core. The moderator may be liquid hydrogen or deuterium at about 30 K. Occasionally, liquid methane is also used at temperatures of about 100 K. The cold neutron absorption cross-section for most elements is about two to three times greater than that for thermal neutrons (1/$v$ behavior).

Owing to their long wavelength, about 0.3 nm, cold neutrons can be bent out of the flight path followed by higher energy radiations by using curved neutron guides. As a consequence, such cold neutron beams display a much lower $\gamma$ and fast neutron background. Figure 4 shows the Cold Neutron Research Facility at NIST.

### 3.2.4 Neutron Spallation Sources

The operation of a neutron spallation source is, in principle, similar to that of an X-ray tube. Protons are accelerated to a high energy, in the range of hundreds of megaelectronvolts (typically 800 MeV up to 1 GeV) and directed on to a heavy metal target, such as uranium, tungsten, lead or a liquid metal (mercury). The result is excitation of the target nuclei. Their de-excitation is accomplished by the emission of several neutrons per incident proton (the number shows an energy dependence and may reach 30). Most of the neutrons produced have energies similar to those of a fission spectrum.

Neutron spallation sources can be continuous or pulsed. A typical value of the neutron flux from a continuous spallation source is $10^{13} - 10^{14} \text{n s}^{-1} \text{cm}^{-2}$.

Figure 5 shows the Paul Scherrer Institute spallation neutron source SINQ.

### 3.3 Shielding

The shielding of a PGNAA facility must be designed according to the neutron source used. Shielding problems for on-line systems are completely different from those of an analyzer installed at the end of a neutron guide tube in a reactor hall. The shielding has two major functions: reducing the detector background so as to enhance the signal to background ratio and guaranteeing radiological safety.

Radiation coming directly from the neutron source as well as that originating in interactions within the sample and components of the system (structure, shielding) can be classified in four groups: (1) fast and epithermal neutrons, (2) thermal and cold neutrons, (3) primary $\gamma$-radiation and (4) secondary $\gamma$-radiation.

#### 3.3.1 Fast and Epithermal Neutrons

The absorption cross-section of fast and epithermal neutrons is small for all materials. For this reason, it is necessary to slow down the neutrons before capture. The most effective shield for these neutrons is a mixture of a hydrogenous material and a thermal neutron absorber.

#### 3.3.2 Thermal and Cold Neutrons

A few elements, such as boron, lithium, cadmium and gadolinium, have a high cross-section for thermal and cold neutrons. Compounds of these elements can be used to obtain an effective shielding against these neutrons. Neutron absorption in boron and cadmium is followed by the emission of $\gamma$-rays. This emission must be taken into account in the design of the shielding of the facility.

#### 3.3.3 Primary $\gamma$-rays

Primary $\gamma$-rays are emitted directly by the neutron source. The problem is particularly acute in on-line analyzers using isotopic neutron sources. The source is generally surrounded by a layer of a strong $\gamma$-ray absorber such as lead or bismuth.

#### 3.3.4 Secondary $\gamma$-rays

Secondary $\gamma$-rays originate in $(n,\gamma)$ or $(n,n\gamma)$ reactions that take place within the sample or in shielding and structural materials. Only $\gamma$-rays from the sample directed towards the detector are wanted for the analysis. Adequate shielding must be provided to absorb all other $\gamma$-rays.

#### 3.3.5 Composite Shielding

A good shielding material for neutrons is a mixture of a hydrogenous material and a good thermal neutron
Figure 4 Experimental facilities around the NIST Reactor. A PGNAA facility is represented. (Reproduced from Paul et al.\textsuperscript{12} with permission.)
absorber. Polyethylene with addition of boron or lithium has proven to make a good shielding because of the physical and chemical properties of the composite: high density of hydrogen atoms, chemical inertness and ease of machining. Lithium–polyethylene materials are very useful as detector shielding because lithium generates no capture $\gamma$-rays. Other hydrogenous materials, such as water or paraffin, are not advisable for industrial applications because of fire hazards and the possibility of leakage that can jeopardize safety.

A combination of lead and boron–polyethylene makes a material with good shielding properties for mixed neutron–$\gamma$ fields.

### 3.4 Detectors

The criteria for the choice of a $\gamma$-ray detector must take into consideration efficiency, resolution, sensitivity to neutron damage and maintenance.

Essentially two types of detector are used in PGNAA. Scintillation detectors based on a thallium-doped sodium iodide detector, (NaI(Tl)), or a bismuth germanate detector (Bi$_4$Ge$_3$O$_{12}$), (BGO), and solid-state germanium detectors, normally the n-type hyper-pure germanium detector (HPGe). Resolution, efficiency and maintenance care are different for the two detector types.

The HPGe detector shows the best resolution, approximately 0.1% fwhm (full width at half-maximum). The NaI(Tl) scintillator has a resolution of about 5% at 2 MeV, or 3% at 10 MeV; the BGO scintillator has the poorest resolution, about a factor of two lower than that of NaI(Tl). The resolution of the HPGe detector enables the separation of closely spaced $\gamma$-lines in complex spectra.

Regarding efficiency, HPGe detector units currently used normally have lower efficiencies than BGO and NaI(Tl) detector units. However, HPGe detectors can have relative efficiencies (compared to a standard NaI(Tl) detector) of the order of 1, if a large enough germanium crystal is used, with the corresponding high cost. The HPGe detector is the most sensitive to neutron interactions within the crystal that promote the formation of traps causing resolution degradation. Owing to the mechanism of transport of charged particles inside the crystal, the n-type detector is less sensitive to neutron damage than the p-type.

Finally, HPGe detectors must be operated at low temperature (100 K) requiring expensive maintenance services. This is a drawback for on-line applications in industry.

Frequently an association of different detectors is used to optimize the arrangement (HPGe/NaI(Tl) or HPGe/BGO).

Detectors used for on-line industrial PGNAA are in general scintillation detectors. Reactor-based analyzers predominantly use HPGe detectors.

### 3.5 Signal Processing and Data Handling

The main objectives of signal processing and data handling at a PGNAA facility are to maximize the pulse throughput rates and minimize the $\gamma$-ray background without detriment to the energy resolution.

The characteristics of the signal processing system must be adapted to the type of detector and to the expected $\gamma$-ray count rates. Signal processing and data handling are carried out by a $\gamma$-spectroscopy unit.

The basic components of the $\gamma$-spectroscopy unit are the preamplifier, amplifier, analog to digital converter (ADC) and multichannel analyzer (MCA).

The function of a preamplifier is to extract the signal from the detector without significantly degrading
the intrinsic signal-to-noise ratio. The preamplifier is located as close as possible to the detector to minimize noise.

A germanium detector represents an extremely high capacitive impedance source \((10 \, \text{G}\Omega, \, 10–50 \, \text{pF})\), generating a small charge \((Q = 2.7 \times 10^{-13} \, \text{C})\) in the detection of a 5-MeV particle. The small output signal requires that the preamplifier does not add appreciable noise.

The absorption of a \(\gamma\)-ray by the detector produces a current pulse at the preamplifier input. The preamplifiers are typically of charge sensitive configuration and are coupled to the detector through the gate of a field effect transistor (FET). Two types of these preamplifiers can be used with Ge detectors: one employs the dynamic charge restoration method (resistor capacitor feedback) and the other the pulsed charge restoration method (pulsed optical or transistor reset) to discharge the integrator.

In many high count rate and high-resolution applications the transistor reset preamplifiers (TRP) offer the best performance.

Nowadays advanced hybrid-electronics manufacturing capability allows the incorporation of the detector element, preamplifier and high-voltage filter into a compact streamlined system.

Where the resolution is not a vital system parameter it is not necessary to use Ge detectors. In their place scintillation detectors can be used. A scintillation detector coupled to a photomultiplier tube generates moderately large signals at the output thus relaxing restrictions on the noise contribution from the preamplifier. They can be also associated with charge sensitive preamplifiers.

A main amplifier with sufficient linearity and large enough bandwidth extracts the energy information from the preamplifier output and converts it to a shape that can be easily analyzed by an ADC. The first stage of the amplifier (differentiator) reduces the decay time and blocks the low frequency or direct current components in the input signal. The following stage (integrator) recovers the energy information from the signal. This yields Gaussian-shaped pulses. The amplitude of each pulse is directly proportional to the energy of the \(\gamma\)-radiation.

To process an incoming pulse completely the amplifier must be adjusted for a time constant (TC) about 10 times the input pulse rise time. A shorter TC stops the processing before it has reached its maximum amplitude, which means loss of resolution in the data. But a longer TC means longer amplifier processing time, which reduces the throughput capabilities of the amplifier: if a new pulse reaches the amplifier before processing the previous one, a pile-up occurs and the piled up pulses are invalid events. Although there are ways to prevent the processing of these pulses, the net effect is decreased system output.

As a shorter shaping TC minimizes pile-up, a TC of 2 \(\mu\)s is recommended for good resolution with Ge detectors. Its maximum throughput capability is just under 20 kcps (kilocounts per second), which is achieved at an input count rate of about 50 kcps. If the input rate exceeds that value, throughput actually decreases owing to pulse pile-up.

For high count rates the use of a gated integrator (GI) will allow a gain of the order of 10 kcps in throughput.

In order to ensure that the piled-up events are not processed by the ADC, additional circuits must usually be considered. These circuits are called pile-up rejector/live time corrector circuit (PUR/LTC). When a new pulse arrives before the previous one is processed, the new pulse is rejected.

The ADC unit converts the amplitude of each event into a digital value to be processed by the MCA or computer. Two types of ADC are available: the Wilkinson ADC and the fixed conversion time (FCT) ADC. The FCT ADCs can offer conversion times significantly shorter than those from the Wilkinson type at least for higher energy events. The choice depends on the specific application taking into account channel resolution and signal amplitude.

The MCA or a personal computer-based MCA acquisition board collects and stores the data, provides its visualization on a monitor, performs mathematical operations to generate the final results and transfers the raw and/or the treated data to an external storage device.

Current cheap memory circuitry provides adequate numbers of data channels and counting capacities as well as short enough data storage times (no more than a couple of microseconds) to deal with the highest count rates encountered in practice.

Hanna et al.\(^{[30]}\) and Wormald\(^{[31]}\) proposed the use of compound detectors for Compton suppression and pair spectrometry. The use of coincidence/anticoincidence techniques with compound detectors can provide simpler spectra by selecting only the useful events. Pair production and Compton scattering are the most important interactions for high-energy \(\gamma\)-rays. If the interaction occurs within the sensitive volume of the detector and the resulting secondary \(\gamma\)-rays escape the detector, a smaller amplitude pulse is recorded.

Schematically, pair spectrometers use three detectors: a central one in which the primary radiation is detected by pair production, and two others for detecting the 0.511-MeV annihilation photons. An event is recorded by using coincidence techniques if a photon of \(E_{\gamma} > 1.022 \, \text{MeV}\) is registered in the central detector and, simultaneously, two 0.511 MeV photons are detected in the others. This method improves the high-energy tail of the spectrum. Wormald proposed a close packing array of cylinders or
hexagonal prisms to form a large collecting area adapted to the shape of the sample.

The Compton suppression spectrometer uses antico-incidence techniques to eliminate events resulting from Compton scattering: only signals which do not have a coincidence signal in another detector are recorded. This technique greatly simplifies the low-energy part of the spectra. A γ-ray spectrometer operating simultaneously in Compton suppression and pair production modes acquires information in three modes: single mode, Compton suppression mode and pair mode. Analysis of the complex γ-ray spectrum can be performed by comparing the three spectra. The spectrometer performance is enhanced.

A wide variety of application programs is available for data handling of the spectra (nuclide identification, background and interference corrections, peak intensity and percent weight content calculation).

4 INSTRUMENT DESIGN AND CALIBRATION

The gauge response of a PGNAA analyzer is determined in a complex manner by the system parameters — geometry, source activity and neutron energy spectrum, and detector efficiency — and by certain properties of the analyzed sample such as bulk density and water content. It follows that the count rate caused by a given γ-ray line is a nonlinear function of the concentration of the element to be measured.

The density and the dimensions of the sample have a direct effect on reaction rates in the sample volume and on the attenuation of γ-rays and thus on the γ-count rate at the detector. For a fixed geometry and composition of the sample the thermal neutron flux depends on the bulk density. When the density increases, the thermal neutron distribution is “compressed” spatially with a higher maximum shifted towards the region of the sample adjacent to the neutron source. On the other hand, the relevant γ-rays on average travel a longer way to the detector inside the sample and are subject to a stronger attenuation. These two effects act in opposite directions upon the γ-count rate and can cancel each other for particular geometries.

Furthermore, the hydrogen content of the sample may also have a significant effect on the neutron flux distribution.

In principle, the composition of an unknown sample can be derived by solving Equations (3) or (5). In this direct or absolute method the concentration of each element is calculated using fundamental parameters, such as cross-sections, number of photons emitted by the element per neutron captured, detector efficiency, γ-ray attenuation coefficients in the sample and solid angle viewed by the detector.(32,33) However, this method is only applicable in a small number of cases owing to uncertainties in the available microscopic nuclear parameters, the unavailability of others and the influence of composition, density and sample volume on the count rate from a given γ-ray line. In activation analysis of large samples a number of correction factors must be applied (neutron absorption and moderation, γ-ray attenuation within the sample and detector efficiencies).

The simplest case is that of thin samples irradiated in a thermal or cold neutron beam. Neutron scattering and γ-absorption in the sample are, then, negligible thus reducing the influence of sample composition and homogeneity on the count rate.

The problem becomes more complicated for on-line gauges using isotopic neutron sources and large samples. Generally, there is neutron thermalization inside the sample so that the thermal neutron flux distribution is dependent on the sample composition, particularly on hydrogen content (moisture) and bulk density.

There are, in principle, several methods for calibrating a PGNAA gauge.

4.1 Experimental Calibration

Experimental calibration establishes the correlation between the γ-ray peak areas and the known chemical composition, density and water content of the samples. The experimental determination of the calibration curves demands long laboratory work, using a large number of standards with well-known compositions, matrix and geometry that closely match those of the sample. (34) The variation in a given parameter can affect the γ-count rate due to a given element, although the concentration of the element remains unchanged. It is a very time-consuming approach, because new standards must be prepared for each sample type.

4.2 \( k_0 \) Method

The \( k_0 \) method is used extensively in delayed NAA. (35) The \( k_0 \)-factor is the ratio of the absolute sensitivity divided by the detection efficiency of the γ-rays of the element to be measured compared with that of a comparator element, \( s \), Equation (9):

\[
k_0 = \frac{R_j}{R_s} \frac{\rho_j}{\rho_s} = \frac{\theta_j I_j \sigma_j / M_j}{\theta_s I_s \sigma_s / M_s}
\]

where \( \theta \) is the isotopic abundance of the nuclide.

In the absence of significant γ-ray self-absorption and for elements with neutron cross-section varying as \( 1/\nu \),
the $k_0$-factor is independent of neutron energy, sample matrix and geometry.

Measurement of $k_0$-factors allows in principle accurate determinations of relative concentrations of every element contained in the sample without the use of the comparator. In effect, the relative concentration of element $j$ to element $i$ in the sample is given by the formula, Equation (10):

$$\rho_{j,i} = \frac{m_j}{m_i} = \frac{R_{j,i}/\varepsilon_{j}k_{ij}}{R_{i,i}/\varepsilon_{i}k_{ii}} \quad (10)$$

When the concentration of one of the elements is known, the absolute concentration of any other element can be assessed. Otherwise it is necessary to measure only the sample and a single standard of similar properties (geometry, neutron scattering and $\gamma$-absorption), containing the comparator element to determine absolute concentrations.

There are some problems that can affect the accuracy of the $k_0$ measurements. Among them are deviations from the $1/v$ behavior of the neutron cross-sections, gamma attenuation in thick samples or with large concentrations of high-$Z$ elements and heterogeneities in the sample.

The $k_0$ method has been applied by several authors to PGNAA measurements.\(^\text{36–39}\)

### 4.3 Monte Carlo Library Least Squares Technique

Gardner et al. have developed the Monte Carlo library least squares method (MCLLS) for PGNAA.\(^\text{40–42}\)

According to this model the PGNAA gauge is a "black box": The gauge response, $R$ is represented by the function, Equation (11):

$$R = f(x,u,v,w,\ldots) \quad (11)$$

where $x$ is the parameter to be measured and $u,v$ and $w$ represent variables that characterize the measurement interferences. Then, Equation (12):

$$x = F(R,u,v,w,\ldots) \quad (12)$$

In the linear least squares (LLS) model the spectrum of the sample is a linear combination of individual components. The content of each channel can be expressed as, Equation (13):

$$b_i = \sum_{j=1}^{m} x_ja_{ij} + E_i \quad i = 1, n \quad (13)$$

where $b_i$ is the unknown sample spectrum or counting rate in channel $i$ of the sample; $x_j$ is the amount of component $j$ in the sample; $a_{ij}$ are the library spectra or counting rate per unit amount of component $j$ in channel $i$; and $E_i$ is the random error in channel $i$ due to statistical counting rate fluctuations.

If the system is linear, i.e. if the gauge response to an individual component does not depend on other parameters, the concentration, $x_i$ can be obtained by minimizing the reduced chi-square with respect to each amount.

However, as the PGNAA analyzers are usually nonlinear, the MCLLS approach has been developed. This is an iterative method that requires that a very accurate Monte Carlo code enables the calculation of the spectra of a sample given its composition, density and geometry. To this end the entire arrangement and the sample are simulated.

Simulations are performed in order to generate the elemental library spectra of all elements present in the sample. The model consists of the following steps:

1. The Monte Carlo code generates the pulse height spectrum of a sample whose composition and density are similar to that of the unknown sample.
2. The prompt $\gamma$-ray spectrum for each element is recorded separately to serve as a library spectrum.
3. The linear library least squares analysis is then performed using the spectra of the unknown sample and the calculated library spectra. The elemental composition obtained is compared with the initially assumed values.
4. If the calculated elemental composition of the unknown sample is close enough to the values assumed for the Monte Carlo simulation, these are taken as the final measured values. If not, the LLS values are taken for the next iteration and steps 1 through 3 are repeated until the linearity assumption is valid.

### 4.4 Monte Carlo Simulation of Calibration Curves

Another method relies on the Monte Carlo simulation of the measuring arrangement with samples having different compositions, densities, water contents and thicknesses, in order to establish the correlation between the count rate for unit concentration of an arbitrary element and the sample parameters.\(^\text{43}\) A comparison is then carried out between the simulated calibration curves and the experimental results obtained with a few standards. A regression analysis is carried out to adjust the simulated calibration curves to the experimental points. Although Monte Carlo simulation studies do not entirely suppress the need to carry out experimental calibration work, they considerably reduce the number of calibration standards required. This method has been used by
4.5 Design Optimization

The crucial part of the design of a PGNAA system is that of ensuring a well-defined correspondence between the output of the system and the elemental composition of the sample. Design optimization is particularly important in the case of equipment for field use with isotopic neutron sources. With fast neutron sources, the thermal flux within the sample volume strongly depends on the moderating properties of the sample, which in turn depend on its density and the number of hydrogen atoms per unit volume, i.e., the water content. On the other hand, the average path length to the detector of \( \gamma \)-rays generated in the sample strongly depends on the sample dimensions. Thus the \( \gamma \)-ray count rate at the detector depends on the sample bulk density and dimensions and on the spatial distribution of the thermal flux.

The purpose of design optimization is to reduce the complexity of the functional dependence of the system response relative to the chosen calibration parameters. This can be achieved in a certain range of sample parameters by acting on the sample geometry, namely the sample thickness, and on the effective neutron source spectrum modified by the introduction of a moderating material around the source or between source and detector, which will substantially influence the thermal neutron flux and its spatial distribution inside the sample.

Monte Carlo simulation is a useful method for speeding up design work and system optimization. The influence of the different parameters on the specific count rate from an element can be established by means of the simulation. Optimum design parameters mean that the gauge response is less sensitive to measurement interferences, such as the ones referred to above (fluctuations of density and water content). To reach this objective, the variance of the measured variables must be minimized with respect to both the gauge response variance and the variances of each measurement interference (see Equation 12).

5 APPLICATIONS OF THE METHOD

5.1 Introduction

PGNAA is a powerful analytical technique that can provide accurate information about the elemental composition of materials in a broad range of cases: raw materials, mineral exploration, contaminants, detection of forbidden products, such as drugs and explosives, inspection of containers (detection of plutonium) and applications in health care. In the following sections, the main fields of application of the method are briefly reviewed.

5.2 Borehole Logging

Since the early 1980s, the most interesting advances in nuclear logging techniques concerned the development of spectroscopy techniques, especially for the analysis of \( \gamma \)-ray spectra. Later on, neutron sources coupled to energy-sensitive detectors were used to observe \( \gamma \)-rays from neutron-induced reactions.

Nowadays, spectroscopy of \( \gamma \)-rays from thermal neutron capture and the inelastic scattering of fast neutrons is commonly used in the study of wellbore geophysics. In this type of well logging, a gauge consisting of a neutron generator or a radioisotopic fast neutron source, and \( \gamma \)-ray detectors is introduced through the formations in boreholes. There are applications for exploration and exploitation of mineral resources (oil, gas, and coal) as well as for the study of geochemical processes.

The main interest of the oil and gas industry in this technique derives from its ability to locate porous zones that may contain hydrocarbons and are free of clay minerals whose presence would inhibit fluid flow. At the same time, it must be ensured that oil and gas production do not contaminate potable water supplies. The coal industry is interested in in situ control of coal quality.

The set of detectable elements provides valuable information on the nature of rock matrix or geological formation. Previously, this information could only be obtained through discrete core analyses.

However, the proper determination of elemental concentrations requires reliable information on geophysical parameters as well as specific spectrometric information related to the individual elements. Several approaches have been developed.

Elemental concentrations obtained from logging measurements have been routinely used to provide sedimentary mineralogy, cation-exchange capacity, permeability and other rock and fluid properties. A comparison between mineralogy derived from logging measurements and that derived from laboratory analyses of core samples is shown in Figure 6.

Information from borehole logging during coal exploration can give an early indication of coal quality by allowing the direct determination of the concentration of sensitive elements and the derivation of important

economic parameters such as ash content and calorific value.

5.3 Industrial On-line Applications

On-line industrial applications of PGNAA are particularly important in the quality control of coal and in the fabrication of cement. Equipment for bulk analysis of coal and cement is presently commercially available. Other on-line applications in raw material control have been implemented, e.g. the determination of Al in bauxite ores or conveyor belt sorting of aluminum alloys in scrap.

The PGNAA technique surpasses the X-ray fluorescence (XRF) technique owing to the higher penetrating power of the neutron–gamma radiation, which as a consequence has the potential to analyze the whole bulk of the material stream. In these applications radioisotopic sources (generally $^{252}$Cf) or neutron generators are used.

The raw material can flow through a vertical chute where the analysis process occurs; generally the chute is lined with an extremely low-friction material to ensure plug free operation. Alternatively, the raw material can be conveyed on a belt. In this case physical integration of the equipment in a previously existing process line is simpler and less costly. Problems related to “dead zones” which always appear in the vertical chute are also avoided in this configuration.

The use of coal as an energy source has severe environmental consequences (ash and SO$_2$ emissions). Good quality control in all phases of the coal fuel cycle will limit the adverse effects. PGNAA can be used in all phases of the coal cycle: mining, coal preparation and power station operation, for the determination of ash, moisture content and specific energy. Among the major coal elements, hydrogen and iron give the best response; sulfur and many of the ash elements (Si, Al, Ti, Ca, Mg, Na, K) are also satisfactorily detected. Carbon responds poorly; however, as its concentration is high it can be detected. Oxygen can hardly be detected in the $\gamma$-spectrum due to the element’s very small thermal neutron capture cross-section. However, oxygen and carbon can be easily detected using $(n,n'\gamma)$ reactions, whose threshold energies are, respectively, 6.13 MeV and 4.44 MeV. This implies the use of a 14-MeV neutron generator or of $^{241}$Am-Be as the neutron source.

Figure 7 shows an experimental prompt γ-ray spectrum of a coal.

The cement industry is fundamentally interested in the measurement of silicon, aluminum, iron and calcium oxides. All the elements involved (except oxygen) can be determined by PGNAA.

The most common application in the fabrication of cement is raw mix proportioning, with the analyzer positioned just ahead of the raw mill. Real-time results can be used to make frequent adjustments of the component feeders to keep the raw mix close to reference composition; another application is the analysis of raw material as it enters the preblending pile. As an alternative to mechanical samplers, analyzers can reduce maintenance and labor costs. A third application is the sorting of raw material coming from the quarry. When synchronized with a downstream diverter, the analyzer can be used to sort one-minute increments of material into save or reject piles.

5.4 Medical In Vivo Applications

In vivo neutron activation analysis (IVNAA) is a unique direct in vivo method for the multielemental analysis of the living human body. Various other radiation-based techniques (radiography, isotopic imaging, radiotracer dilution) reflect only relative changes in tissue density or volume. Table 6 shows the elements measured by activation analysis.

The prompt γ-variety of IVNAA can provide data on the total or partial body content of the following elements: oxygen, carbon, hydrogen, nitrogen, calcium, sodium, chlorine, silicon, iron, cadmium and mercury.

Although PGNAA instruments were initially developed in nuclear research laboratories, methodologies have advanced to a stage where facilities were designed and built exclusively for clinical application in hospitals and health centres.

The choice of the neutron source is based on elements to be measured, the required degree of uniformity of the activation, the acceptable level of accuracy and the admissible radiation dose. Cf and Pu-Be are the most used sources; some facilities are equipped with neutron generators or cyclotrons. Large NaI(Tl) scintillators are generally used as detectors, although in certain facilities germanium or BGO detectors are preferred.

Considerable effort has been expended in reducing the absorbed dose without decreasing the precision of results. The substitution of Pu-Be sources by Cf contributes to this end. The range of exposure doses in existing facilities depends in part on the element to

Be analyzed, the precision required and the detection sensibility of the counting system. The Swansea system is shown in Figure 8. The dose is often less than, or comparable to, many routine diagnostic radiographic procedures.

The initial application that has influenced the subsequent development of IVNAA is the determination of total body calcium content in patients suffering from various metabolic diseases. Since calcium is predominantly located in the skeleton, a measure of this element would provide a direct examination of the total skeletal mass. Clinical research studies have investigated a number of metabolic disorders such as renal osteodystrophy, Paget’s disease, Cushing’s syndrome, acromegaly, thyroid and parathyroid disorders, myotonic dystrophy, thalassemia and alcoholic cirrhosis.

The body nitrogen measurement provides a direct determination of body protein, which is the essential component of the body’s lean tissue mass. Changes in protein mass can reflect changes in nutritional status. Hence clinical studies involving nitrogen measurements in patients with progressive diseases may be important in the following cases: postoperative surgery, protein malnutrition, cancer renal failure, cardiovascular disease, total parental nutrition, obesity and growth deficiencies.

Body carbon measurements can provide an index of the body fat.

Cadmium measurements have been carried out in industrial workers. Kidney concentrates cadmium and has been identified as the initial target organ in toxicological studies. The association between cadmium burdens and various diseases related to kidney malfunctions have also

---

been investigated. Several studies involving nondiazyed patients in renal failure have shown that cadmium was a cofactor in the cause of the renal disease.

5.5 Determination of Environmental Contaminants
Elemental analysis of toxic elements in contaminated materials is essential for solving environmental problems. PGNAA can also be applied to this purpose in the determination of major and minor elemental components and even of trace elements.

Dulloo et al.\(^{(57)}\) used a 14-MeV pulsed generator for the nondestructive assay of mercury, cadmium and lead. The DLs for a 600 s run are 15 ppm, 170 ppm and 8600 ppm for Cd, Hg and Pb respectively.

Yonezawa et al.\(^{(23)}\) carried out multielement analysis of environmental samples by PGNAA with cold and thermal neutrons in a reactor facility. Cd was detected in mussels, river sediments, pond sediments, vehicle exhaust particulates and unpolished rice flour; Hg was detected in human hair.

Hiem and Tan\(^{(22)}\) used the technique for analyzing the concentration of Al, Fe, Ti, Si, Ca and K in airborne dust samples.

5.6 Explosives and Drugs Detection Systems
Considerable progress has been made in research and development of nuclear-based techniques for the detection of explosives and drugs. The technique must be noninvasive, sensitive to the smallest effective amounts of explosives and drugs and give rise to a minimum of false alarms. An effective contraband inspection system must be capable of determining the relevant chemical elements and their spatial distribution in the inspected object.\(^{(58)}\)

Chemical explosives have high nitrogen and oxygen contents. Pure narcotics are characterized by high content of H and C, moderate content of O and small content of N. However, narcotics hydrochlorides also contain small amounts of Cl. While high nitrogen density is a good indicator of explosives, the detection of a low oxygen to carbon ratio combined with the presence of N and Cl is a strong indication of the presence of drugs.

The PGNAA technique enables the three-dimensional mapping of explosives and narcotics in luggage. This is accomplished by irradiating parts of the interrogated object with short pulses of fast monoenergetic neutrons (Figure 9). The three-dimensional distribution can be obtained by scanning the sample.\(^{(59)}\)

5.7 Other Applications
Many other applications have been carried out in different fields using PGNAA.

Anderson et al.\(^{(60)}\) described the determination of H, B, Cl, K, Na, S, Ca and Cd in foods using a thermal neutron beam. The advantage of this type of analysis lies in its sensitivity to elements of nutritional or toxicological interest while no sample preparation is needed, thus eliminating the risk of volatilization losses.

Kuno et al.\(^{(61)}\) applied PGNAA to the determination of the concentration of B, H, S and Si in on-shore sediments in order to investigate the distribution and migration of chemical elements. The measurements were complemented by DGNAA results.

Caffrey et al.\(^{(62)}\) applied a portable PGNAA device with an isotopic source to the identification of the contents of munitions, chemical storage containers, chemical warfare materials in stockpiles, etc.

Prettyman et al.\(^{(63)}\) investigated the use of the technique as a diagnostic tool related to matrix characterization for nondestructive assay and plutonium surveillance. The technique can help to confirm item descriptions (for example, plutonium chloride versus plutonium oxide).

Spyrou et al.\(^{(64)}\) proposed a method to determine the concentration of a large number of elements by measuring the prompt or delayed γ-rays and applying the principles of reconstructive tomography to obtain the spatial distribution of elemental concentration in a selected plane or slice through the sample. This method has been employed in the examination of radioactive waste as well as in elemental analysis of biomedical and bioenvironmental samples.

The contents of major and some trace elements in large archaeological materials have been determined by Sueki et al.\(^{(24)}\)
6 PRESENT TRENDS OF DEVELOPMENT

According to Gardner(52) "PGNAA is a rapidly emerging important new technology and measurement approach". However, further development of its applications in different branches of human activity require improvements in neutron sources, signal processing and data handling as well as in nuclear data.

The introduction of a new point source generator based on the IEC principle may have a promising future in on-line field applications of PGNAA. Apart from sharing the on-off switching capability with conventional neutron generator devices, it offers longer life and lower costs.

Industrial on-line process control requires short response times. For a PGNAA analyzer this means, normally, high count rates. High-rate data acquisition systems must be improved.

Enhancement of signal to background noise ratio leads to lower statistical uncertainty of the results thus contributing to reducing response times. This objective can be achieved by proper system design optimization. Monte Carlo methods can play an important role in this respect.

More accurate measurements and thus better data regarding microscopic nuclear parameters, such as cross-sections, number of photons emitted per neutron captured by the relevant isotope and \( \gamma \)-ray attenuation coefficients in different materials are important for simulation studies carried out with a view to optimizing design and calibration of PGNAA analyzers.

Although certain physical constraints (neutron flux perturbations and \( \gamma \)-ray attenuation) are difficult to overcome, the development and application of the \( k_0 \) method to large samples would be welcome.

The MCLLS technique, which has been applied to coal, cement raw materials, oil well logging, vitrified nuclear waste and conveyor belt sorting of aluminum alloys in scrap, can also be successfully applied to other fields.

The nuclear imaging technique using a pulsed fast neutron analyzer for the detection of explosives concealed in airline luggage has potential application in the future to a variety of other situations.

Radiochemical neutron activation analysis (RNAA) is a method for trace-element determination based on the measurement of an indicator radionuclide, chemically separated from a neutron-activated sample. Unlike instrumental neutron activation analysis (INAA) the RNAA is therefore not a nondestructive method, and at the same time the amount of work put into the analysis of each sample makes RNAA much more expensive than INAA. This is the cost that has to be paid for determining selected elements at much lower concentrations and superior accuracy, while maintaining matrix independence and most of the other excellent characteristics of INAA. One of these characteristics is the small self-shielding during irradiation with neutrons, which opens the possibility of analyzing also large samples without any pretreatment.

Particularly for the lowest levels of trace elements RNAA provides several important advantages over alternative analytical methods:

- a) the absence of a reagent blank, and
- b) the corresponding insensitivity to contamination after activation
- c) the controlled addition of carrier to avoid losses by adsorption etc., and
- d) the corresponding possibility of determining chemical yield or recovery.

When carefully and thoughtfully carried out, RNAA qualifies as a so-called definitive method, one of the reasons being its direct traceability to a comparator of the pure element to be determined.

1 INTRODUCTION

The use of neutrons for analytical purposes goes back to the classical paper by Hevesy and Levi,\(^\text{[1]}\) who discovered in 1936 in Copenhagen that activation of a sample of presumably pure Y\(_2\)O\(_3\) by means of a Ra–Be neutron source gave rise to a radionuclide that could only be attributed to Dy; by comparing with samples of pure Dy they were even able to determine the actual quantity of Dy in the particular sample.

1.1 Principle and Definition of Radiochemical Neutron Activation Analysis

Although himself a chemist Hevesy never applied radiochemistry to any activated samples for analytical purposes; this was first done by Seaborg and Livingood,\(^\text{[2]}\) who determined Ga after the addition of carrier and radiochemical separation of iron activated at the Berkeley cyclotron.

RNAA is a method for the determination of elements, and its full power was not realized until after the second World War, when the availability of nuclear reactors was brought to the attention of the analytical community. A clear presentation of the principles of RNAA, including carrier addition and yield determination, was

---

*Current affiliation: Technical University of Denmark, Lyngby, Denmark
first made by Boyd, (3) who still provides the fundamental description of what was later referred to as comprehensive RNAA: (4)

1. activation with neutrons
2. carrier addition
3. radiochemical separation
4. measurement of activity
5. determination of yield.

After half a century RNAA has reached maturity, the principles are well understood and no major technological developments are expected to take place in the foreseeable future. At the same time, it is also improbable that any other method will be found that could provide the same special characteristics so valuable for ascertaining the quality of trace element analysis.

1.2 Relationship to Instrumental Neutron Activation Analysis

The outstanding characteristic of neutron activation analysis in comparison with other methods of analysis is the timescale associated with the lifespan of the excited species or characteristic radionuclides, often referred to as indicators, which permit the introduction of a chemical separation between the end of activation and the beginning of measurement.

In purely instrumental neutron activation analysis this decay period is only used for simple physical operations, such as separating the sample from its container, taking an aliquot by volume or weight, cleaning the surface of the sample or adjusting its shape or volume before measurement is begun. In INAA the preservation of the integrity of the sample permits the determination of many elements in the same sample.

The radiochemical separation carried out during the decay period is characteristic of RNAA and serves to reduce or eliminate unwanted radionuclides interfering with the measurement of the indicator, so as to minimize the uncertainty associated with the determination of a particular element. RNAA is therefore basically a method for the determination of only a small number of elements in the same sample.

Over the years successful attempts have been made to reduce the need for radiochemical separations by advances in instrumentation for counting, supplemented with the use of γ-radiation or charged particles rather than neutrons for activation. (5) For highest accuracy at the lowest levels RNAA is still needed as a reference method.

1.3 Advantages and Limitations

RNAA is clearly not a nondestructive method, and at the same time the amount of work put into the analysis of each sample makes RNAA much more expensive than INAA. This is the cost that has to be paid for determining selected elements at much lower concentrations and superior accuracy in comparison with INAA, while maintaining most of the other excellent characteristics of this method, see Instrumental Neutron Activation Analysis, including the small self-shielding during irradiation with neutrons, which opens up the possibility of analyzing large samples as well without any pretreatment. (6)

Particularly for the lowest levels of trace elements RNAA provides several important advantages over alternative analytical methods:

1. absence of a reagent blank
2. corresponding insensitivity to contamination after activation
3. controlled addition of carrier to avoid losses by adsorption etc.
4. corresponding possibility of determining chemical yield or recovery.

The presence of a controlled amount of carrier during the radiochemical separation process, regardless of the original content in the sample, makes the a priori precision in the uncertainty budget independent of the concentration of the element to be determined, the determinand, see section 4.4. Any method that has been found to be useful for chemical separation of the indicator element from the material to be analyzed by any other analytical method, could also be used in RNAA.

In this article we are therefore concerned only with the evaluation of the performance characteristics of the potential separation methods (see section 2.3) not with the methods themselves.

When carefully and thoughtfully carried out, RNAA qualifies as a so-called definitive method, (7) one of the reasons being its direct traceability to a comparator of the pure element to be determined.

2 THEORY AND OPERATING PRINCIPLES

The special features of RNAA can be expressed as a combination of separate, almost independent unit operations, and Figure 1 (8) illustrates the entire process from the sample to be analyzed to the result of the analysis.

The RNAA sensitivity $S$ given in Equation (1) for a particular determinand element $X$ is expressed as the number of counts per unit weight of $X$, and it depends upon the half-life of its indicator $T_{1/2}$, the duration of the activation $t_1$, the decay time $t_2$, and the counting time $t_m$

$$S = \frac{C_x(1-e^{-\lambda t_1}) e^{\lambda t_2} (1-e^{-\lambda t_m})}{\lambda}$$

(1)
where \( \lambda T_{1/2} = \ln 2 \), and the rate constant (Equation 2)

\[
C_x = P_i R_c P_m
\]

has to be determined experimentally from a known quantity of comparator.

The rate of formation \( P_i \) is proportional to the neutron flux density during activation, see section 2.2, but its magnitude varies by orders of magnitude from element to element. The recovery \( R_c \) and the detection efficiency \( P_m \) will be discussed later.

Table 1 lists those elements with corresponding indicators which have rate constants larger than that of Zn.\(\text{\textsuperscript{9a}}\)

### 2.1 Sample and Comparator

In RNAA the analytical sample is just as prone to contamination before activation, as it is in all other analytical methods. The characteristic insensitivity to contamination applies only after completion of the activation process, and it is therefore important that any conditioning or preprocessing of a sample be kept at an absolute minimum.

Some reactors require biological samples to be dried or lyophilized before activation in order to reduce formation of gases by radiolysis of the water content; this may, however, require special tracer studies to ascertain that no loss of determinand is incurred.\(\text{\textsuperscript{10}}\) At low levels of determinand any such preprocessing necessitates the introduction of a blank to be analyzed together with a sample in order to monitor possible contamination occurring before activation.

Although it is possible to carry out neutron activation analysis without activating an isotopic comparator together with the sample,\(\text{\textsuperscript{9a}}\) this is rarely done for RNAA. The limited number of elements that can be determined in the same sample makes the use of individual comparators much more attractive, because of the greater freedom it gives with respect to both activation and counting conditions.

A comparator is prepared from a weighed quantity of the element to be determined or a compound with an accurately known stoichiometry,\(\text{\textsuperscript{11}}\) chosen so that no other significant activity will be present at the time of measurement.
The validity of the comparator requires that it be activated under exactly the same conditions as the sample with respect to both time and space. It must be physically as similar as possible to the sample at the time of counting, i.e., after completion of the radiochemical separation: same counting vial, same volume, similar matrix, etc. However, the comparator should not be processed, in order to eliminate any possible risk of loss, which means that \( R_c = 1 \), and the rate constant for the comparator \( C_r^* \) is reduced to Equation (3)

\[
C_r^* = P_i P_m \tag{3}
\]

The comparator need not be identical or even similar to the sample, as long as it is exposed to the same fluence of neutrons. The sample, therefore, can be of any size or shape from up to perhaps several kilograms, to practically weightless quantities, still using the same comparator. In some cases it may be appropriate to weigh the analytical sample, as well as to take an aliquot of the comparator after completion of the activation.

### 2.2 The Activation Process

Activation of a sample by neutrons could be carried out with a number of devices, such as accelerators, cyclotrons, radioactive sources, or even spallation sources; nuclear reactors remain, however, the most suitable source of neutrons for RNAA.

Research reactors are found in many countries, and most of them offer irradiation services for neutron activation analysis with neutron flux densities up to \( 10^{14} \) neutrons cm\(^{-2}\)s\(^{-1} \), which is more than sufficient for the determination of the elements listed in Table 1. More important is the spatial flux homogeneity that is needed to ascertain that samples and comparator irradiated together are exposed to exactly the same number of neutrons.

Irradiation of an element with a relative atomic mass \( A_i \) at a constant neutron flux density \( \psi \) for a period of \( t_i \), produces a specific activity of:

\[
\frac{N_A \sigma \psi (1 - e^{-\lambda_i t_i})}{A_i} \text{ Bq g}^{-1}
\]

where \( \sigma \) is the appropriate cross-section of the element for the formation of a specific radionuclide, and \( N_A \) is the Avogadro number.

The saturation activity achieved after an infinite irradiation time is numerically equal to the rate of formation of the indicator nuclide (Equation 4)

\[
P_i = \frac{N_A \sigma \psi}{A_i} \tag{4}
\]

Some small reactors with modest neutron flux densities like the Canadian Slowpoke type may be so stable in time that sample and comparator need not even be irradiated simultaneously. In most nuclear reactors, however, changes in neutron flux exposure during irradiation may take place as a result of the introduction or removal of other samples, movement of control rods, change of power level, moderator temperature, or virtually intermittent operation, as well as many other things beyond the control of the analyst. These changes will affect indicator isotopes differently because of their different half-lives; however, the simultaneous irradiation of a comparator of the element to be determined, the determinand, will automatically account for such changes.

Subject to the needed sensitivity the duration of irradiation should be kept as short as possible in order to:

1. keep the total activity of the sample low enough for proper handling without excessive shielding and time-consuming use of remote handling equipment;
2. minimize radiation decomposition of the sample, which may result in the loss of halogens, mercury, or other elements, when the irradiation capsule is opened;
3. reduce the influence of long-lived activated matrix components on the choice of counting conditions;
4. limit the nuclear interference from double neutron capture in some elements.

### 2.3 Radiochemical Separation

During the period between the end of activation and the beginning of measurement the analytical sample is subjected to a radiochemical separation, which should be completed preferably within one mean life of the indicator. The performance characteristics of the radiochemical separation therefore must include the time needed to complete the task, which in practice limits the use of RNAA to elements with indicator half-lives in excess of a few minutes.

Sample decomposition in RNAA presents the same problems as in all other methods of chemical analysis to ascertain carrier equilibration the procedure should include a complete oxidation-reduction cycle. The process can hardly be completed in less than several minutes, which is just feasible for \( V \) in human serum with an indicator half-life of 3.8 min, but barely enough for \( AI \) with 2.2 min half-life.

The absorption of a neutron gives rise to the emission of one or more capture \( \gamma \)-rays with energies of several MeV, which causes a nuclear recoil energy of \( 536 \times E_i^2 / A_i \) eV which is enough to break a chemical bond. Because of this Szilard-Chalmers effect the activated atom no longer retains its original position in a chemical entity, and RNAA is therefore incapable of determining any speciation of an element. By
the same token, however, postirradiation carrier equilibrium does not necessarily require complete sample decomposition, but only complete dissolution. This is an important difference from other reference methods, such as isotope dilution mass spectrometry (IDMS), that rely on complete isotopic exchange between an added isotope tracer and the total content of an element in the sample.

The addition of carrier is required not only for all elements that need to be determined, or rather their indicators, but also for some interfering elements, from which a good separation is important. Such a hold-back carrier could prevent adsorption or coprecipitation that might result in poor and irreproducible separation from interfering radionuclides.

The aim of a radiochemical separation is to achieve a high and reproducible recovery of the indicator radionuclide at the same time as a very low yield of all other radionuclides. The efficiency of the separation is expressed by the separation factor,\(^{21}\) \(K\), which, as shown in Equation (5), is the ratio between the yield of the interfering species, \(r_i\), and the recovery of the determinand

\[
K = \frac{r_i}{R_c}
\]  

\((5)\)

\(K\) is usually determined by adding a suitable radioactive tracer together with carriers to an unirradiated sample which is then processed and measured exactly as a normal sample.\(^{22}\) Experimentally determined separation factors are presented in Table 2\(^{23}\) for a simple radiochemical separation of Cu in biological materials. A good separation will have separation factors better than \(10^{-5}\), but in extreme cases a separation factor better than \(10^{-7}\) has been demonstrated.\(^{24}\) It is worth pointing out that the use of highly effective radiochemical separations with good separation factors makes possible the determination of several other elements with less sensitivity than those listed in Table 1, such as Cr, Fe, Mo, and Cd.\(^{22,23}\)

Complete separation of the indicator from all other radionuclides in the activated sample is required when the indicator has to be measured by its emission of \(\beta\)-particles in order to achieve sufficient sensitivity.\(^{25}\) In most cases of \(\gamma\)-emitting indicators a high separation factor is needed only for the dominant interfering elements. Such interference removal is often needed for activated matrix components such as \(^{24}\)Na, \(^{42}\)K, and \(^{82}\)Br that dominate the \(\gamma\)-spectra of activated biological samples for days or weeks after the end of irradiation. Successful removal of \(^{24}\)Na is possible by means of hydrated antimony pentoxide,\(^{25}\) and other matrix indicators may be removed by precipitation with thioacetamide, extraction of Fe with ether, or other conventional methods of chemical separation.\(^{26}\) It should be recalled that nuclear interference from matrix elements cannot be eliminated by a radiochemical separation, but requires a preirradiation separation.

Each combination of determinand element and matrix composition may have its own optimum radiochemical separation method that minimizes the effort and maximizes the quality of the final result. A general discussion of the factors involved in such an optimization must be based on the separation factors needed for the particular analytical task. This paves the way for the use of less specific group separations, the use of scavengers to collect the elements to be determined, adsorption on solid oxides, activated carbon etc. Some of these methods seem to work best without carrier addition, but without determination of the recovery of the indicator these methods would suffer from an intrinsic lack of credibility.

### 2.4 Methodology of Counting

A radiochemically separated sample that contains only the indicator radionuclide could be measured by any suitable instrument with a sufficiently high detection efficiency, and in this respect it would be hard to beat a simple Geiger-Müller (GM) counter or liquid scintillation counter which detects \(\beta\)-particles with close

NUCLEAR METHODS

2.5 Data Processing

The processing of $\gamma$-spectra in RNAA is very different from the methods employed in INAA (see Instrumental Neutron Activation Analysis).

First, we are only interested in the indicator nuclide and therefore need not identify all other radionuclides in the spectrum, unless they contribute to the spectrum in the vicinity of the indicator $\gamma$-energies, such as those listed in Table 1.

We are, however, interested in the best possible quantitation of the indicator with the minimum uncertainty and without interference, even close to the limit of detection. In the evaluation of small-to-invisible photo peaks on a high Compton continuum, the determination of the number of counts that can with a high degree of certainty be attributed to the indicator is best carried out by simple peak integration according to Covell, and not by fitting the small number of counts to an assumed Gaussian or other peak shape.

The optimum choice of peak boundaries for peak area evaluation depends upon the full width at half-maximum (FWHM) and the relative height of the photo peak to the base continuum. The optimum half-width has a limiting value of 0.90758 FWHM for photo peak heights approaching zero, and Figure 2 shows optimum half-widths for peak area integration as a function of relative peak heights and FWHM.\(^{(29)}\)

The FWHM is a function of $\gamma$-energy $E$

$$\left(\text{FWHM}\right)^2 = wE + w_0$$

where the coefficients $w$ and $w_0$ in Equation (7) are determined from the actual spectrum by weighted linear regression of FWHM\(^2\) for the largest photo peaks on their corresponding $\gamma$-energies or channel numbers. These peaks would be the same as used for energy calibration by simple linear regression of $\gamma$-energies on channel numbers and do not necessarily include any photo peak of the indicator nuclide.

The FWHM corresponding to the chosen photo peak of the indicator is now used in combination with Figure 2 to select the peak boundaries for optimum precision of the partial peak area evaluation according to Covell. The partial peak area is then converted to the full peak area by assuming a Gaussian shape with the assumed FWHM, which is a purely mathematical operation that does not change the relative precision of the measurement. The final result of the data processing is the full peak area in counts together with its associated standard deviation, calculated on the basis of a Poisson distribution for each individual channel content. An implementation of this approach has been verified by comparison with IAEA (International Atomic Energy Agency) test spectra with...
known peak areas, as well as with actual spectra with known ratios.\(^{28}\)

The possible interference from other radionuclides is not estimated by attempting to resolve doublets or multiplets, but by the measurement of the effective values \(f\) of potentially interfering elements.\(^{30}\) By irradiating a known quantity of an interfering element exactly like a sample together with a comparator of the determinand, and using the peak boundaries for the determinand, the effective value is determined as the ratio between counts per unit mass of interfering element relative to determinand. For elements with effective values in excess of 0.01 separation factors should be determined in order to specify the assumptions of the RNAA.

Table 2 lists effective values for seven elements suspected of interfering with the determination of Cu by RNAA.\(^{9c}\) This allows the user to judge the performance characteristics of the method for the analysis of actual samples.

Interference from the formation of the indicator nuclide during activation from another element by (n,p), (n,\(\alpha\)) reactions, or by double neutron capture, is usually referred to as nuclear interference and can be corrected for only by the simultaneous activation of an additional comparator of the interfering element.\(^{17}\) A particularly treacherous interference occurs when the indicator nuclide is also produced by fission of uranium, which may necessitate a separate determination of this element\(^{31}\) in order to correct for this positive bias.

Sometimes the absence of interference may be demonstrated by the determination of the same element using two different indicator nuclides.\(^{32}\)

### 2.6 Recovery Correction

The determination of recovery or chemical yield of the analytical separation is an outstanding property of RNAA and enables the method to estimate the true content of the determinand in the sample.

In routine applications of highly standardized radiochemical separations the chemical yields are often determined by adding radioactive tracers of the determinands.
NUCLEAR METHODS

to an inactive sample before performing the separation, exactly as described for the determination of interferences. The use of such a priori chemical yields instead of individual recoveries is justified only when the yields are close to 100% and the correction therefore quite small. \(^{(33)}\)

In research applications, where every analysis might differ from the rest, recovery is usually not quantitative and is susceptible to considerable variation from sample to sample, which means that recoveries must be determined for each individual analysis. In that case much larger corrections for chemical yield can be accepted, while still maintaining statistical control.

A comparison of the amount of carrier in the separated sample with the originally added quantity by almost any analytical method could be used for the determination of recovery, and in many applications gravimetry has been used. However, such chemical methods might jeopardize the principle of not processing the added carrier reference comparator sample, and therefore a direct instrumental method without any additional treatment and a minimum of handling of the separated sample is clearly preferable, and simple radioanalytical methods based on either a short re-irradiation or the addition of a radioactive tracer, are often the methods of choice:

1. With carrier added at the milligram level the irradiation time can be very short, and the measurement of the induced radioactivity can be very simple. \(^{(34)}\)

By simultaneous irradiation and direct comparison between added and recovered carrier there is no need to know the amount of carrier accurately, provided the content in the sample is negligible in comparison to the added quantity of carrier.

2. Addition of a radioactive tracer together with the carrier opens the possibility of determining recovery at the same time as measurement of the indicator. Clearly, the tracer should not be produced by neutron activation and the amount added should be chosen carefully in order not to disturb the measurement. \(^{(35)}\)

A list of radionuclides used as tracers for the determination of individual recoveries of added carrier is presented in Table 3. If they are truly carrier-free they may even be added to the sample before activation, so that any losses that might occur as a result of preirradiation processing would be included in the recovery. \(^{(10)}\)

3. Instead of adding the radioactive tracer to the sample before separation it may be added after completion of the separation and the measurement of the indicator, in order not to cause spectral interference. It is now possible to correct for recovery during separation by comparing the specific activities of the carriers added to the separated sample and the carrier reference comparator sample by using substoichiometric methods. \(^{(36)}\)

It has been proposed that an internal standard of another element be used to correct for recovery; however, this is limited to the cases where this element yields a radionuclide isotopic with the indicator nuclide.

If carefully thought out, the individual determination of recovery for each sample requires very little additional effort in comparison to the radiochemical separation. \(^{(37)}\)

### 2.7 Final Calculation of Analytical Result

The calculation of results obtained by RNAA is basically similar to that of INAA; however, the proper utilization of the various measurements for correcting initial results and estimating their uncertainty may become quite complicated. It is, therefore, strongly recommended that

It has been proposed that an internal standard of another element be used to correct for recovery; however, this is limited to the cases where this element yields a radionuclide isotopic with the indicator nuclide.
calculation be done in the form of a spread-sheet, not only in order to avoid making mistakes, but also because it facilitates the implementation of quality control, as well as the smooth propagation of errors from one stage to the next.

As an example let us pretend that we have carried out RNAA for two determinands in the same sample, and for simplicity let us assume that both can be determined from the same \( \gamma \)-spectrum, but with some interference from one indicator to the other. We also assume that comparators of both determinands were irradiated together with the sample. The data available for calculating the concentration of determinands in a sample may be organized as shown in Table 4.

Calculations are now carried out in the following sequence:

1. Photopeak counts are corrected to count rates at the time of pile-out by multiplication with a decay correction for

\[
\frac{M}{\lambda_1 e^{-\lambda_1 t_c}} = \frac{M}{1 - e^{-\lambda_1 t_c}}
\]

(8)

In Equation (8) \( \lambda \) is the decay constant for the radionuclide associated with the photopeak in question. Decay corrections are conveniently placed in the columns immediately after the counting data:

2. The uncorrected content of 1 determinand in the separated sample and its corresponding standard deviation are calculated as:

\[
\text{content} = AD \times \frac{M}{AM} \times \frac{O}{AO}
\]

and placed in column CA

\[
CV^2 = \left( \frac{N}{M} \right)^2 + \left( \frac{AN}{AM} \right)^2
\]

standard deviation = SQRT(CV^2) \times \text{content}

and placed in column CB

3. The uncorrected content of 2 determinand in the separated sample and its corresponding standard deviation are calculated as:

\[
\text{content} = BD \times \frac{Q}{BQ} \times \frac{S}{BS}
\]

and placed in column CC

\[
CV^2 = \left( \frac{R}{Q} \right)^2 + \left( \frac{BR}{BQ} \right)^2
\]

standard deviation = SQRT(CV^2) \times \text{content}

and placed in column CD

4. Correction of the influence of 2 determinand on the result for the 1 determinand requires the calculation of the effective value:

\[
\text{effective value} = \frac{AD}{BD} \times \frac{BM}{AM} \times \frac{BO}{AO}
\]

and placed in column CE

\[
CV^2 = \left( \frac{AN}{AM} \right)^2 + \left( \frac{BN}{BM} \right)^2
\]

standard deviation = SQRT(CV^2) \times \text{effective value}

and placed in column CF
5. The corrected content of the 1 determinand in the separated sample is now calculated as:

\[
\text{content} = CA - CC \times CE
\]

and placed in column CG

\[
CV^2 = \left( \frac{R}{Q} \right)^2 + \left( \frac{BR}{BQ} \right)^2 + \left( \frac{BN}{BM} \right)^2
\]

standard deviation = \(\text{SQRT} \left[ CA \times \frac{N}{M} \right]^2 + CV^2(CC \times CE)^2 + \left( \frac{AN}{AM} \right)^2\)

and placed in column CH

At this stage it should be checked whether CG is negligible in comparison with the quantity of added carrier; if not the recovery E should be reduced by subtracting their ratio.

6. The real concentration of determinand in the sample material and its uncertainty are finally calculated from the original sample weight and the recovery of the appropriate carrier in the separated sample:

\[
\text{concentration} = \frac{CG}{D \times E}
\]

is placed in column CK

\[
CV^2 = \left( \frac{F}{E} \right)^2 + \left( \frac{CH}{CG} \right)^2
\]

standard deviation = \(\text{SQRT}(CV^2) \times \text{ABS}(CK)\)

and placed in column CL

An example of actual results obtained from the determination of Pt in a reference material from the Bureau Communautaire de Référence (BCR) certified reference material (CRM) 186 pig kidney\(^{(38)}\) is shown in Table 5, which also indicates the spreadsheet columns, from which these results are taken. The indicator for Pt is \(^{199}\text{Au}\), formed by the decay of \(^{199}\text{Pt}\), but also from neutron capture in \(^{198}\text{Au}\), the indicator for gold. The correction for nuclear interference is in this case comparable to the total amount of \(^{199}\text{Au}\) and therefore leads to very large relative uncertainties in the final results for Pt.

Corrections for nuclear interference from uranium in the determination of La, Ce, Sm, Nd, Zr, Mo, Ru, Te, etc. may be carried out in a similar way,\(^{(39)}\) except that the concentration of U in the sample has to be determined separately.

This paradigm can easily be modified to accommodate other situations in RNAA with additional determinands and \(\gamma\)-spectra, using the same general approach to calculation of results and their uncertainties.

Corrections for possible blank values, such as those associated with preirradiation treatment of the sample,\(^{(33)}\) must be carried out by calculating the blank value exactly as if it were a sample and then subtracting from the final result for the sample itself.

3 INSTRUMENTATION

Radiochemical separation requires a radioanalytical laboratory of Type C,\(^{(39)}\) which is essentially just a good quality chemical laboratory with a radiochemical hood and a little shielding to reduce radiation exposure.

Requirements for irradiation facilities and counting equipment do not go beyond those needed for INAA, but the emphasis on some of the features and specifications is shifted because of the nature of the separated sample and the low levels of activity of the indicator nuclides.

3.1 Irradiation Systems

In order to benefit most from the properties of RNAA it should be possible to activate rather large samples without any preceding treatment that might lead to losses or contamination. As with INAA it is important that the entire sample and associated comparators be exposed to identical neutron flux densities for exactly the same time.

This is best achieved in a system that permits rapid transport in and out of the irradiation zone, while providing rotation of the irradiation container during activation.\(^{(40)}\) In order to minimize sample decomposition

the thermal neutrons should be accompanied by a minimum of epithermal and fast neutrons, as well as γ-radiation.

In Figure 3 is shown a drawing of such a facility in the Danish Reactor DR 3, which permits simultaneous irradiation of three containers of about 30 cm³, while they are rotated in a thermal neutron flux density of $3 \times 10^{13}$ neutrons cm⁻² s⁻¹ shielded by 50 mm of bismuth to reduce the γ-ray intensity.

### 3.2 Counting Equipment

A complete radiochemical separation of the indicator nuclide would allow use of the very sensitive but nonspecific detection of β-particles by very simple counting equipment. However, no separation is perfect, and in practice the less sensitive, but high-resolution detection of γ-rays is preferable, wherever possible.

With the availability of germanium semiconductor detectors having efficiencies comparable to, or even surpassing, that of the $3'' \times 3''$ sodium-iodide scintillation detector, the instrumentation for RNAA becomes similar to that needed for INAA with the same electronic equipment and multichannel analyzer with at least 16 K ($K = 1024$) channels.

The detection efficiency $P_m$ determines the sensitivity of determination $S$, while an improved resolution of the detection system improves both the precision and accuracy of the determination by:

1. facilitating the detection of unexpected interferences
2. minimizing the correction for known spectral interferences
3. reducing the standard deviation of the photopeak area
4. improving the detection limit.

Similar improvements may sometimes be achieved by the use of two or more detectors in combination with coincidence/anticoincidence circuitry to obtain spectra providing improved detection limits with only a slight loss of sensitivity.⁴¹

As previously discussed the close counting geometry of the separated sample must be exactly equal to that of the comparator, calling for an accurately reproducible counting position to ascertain exactly equal counting efficiency and coincidence losses for both. A counting assembly with such reproducible counting positions for liquid samples is shown in Figure 4.

The usually low activity of the separated samples makes corrections for dead time and pile-up less critical, and a simple 50–60 Hz pulser with a narrow peak in the highest channels of the spectrum is a reliable way of making such corrections. The use of digital signal processing (DSP) improves resolution at high count rates, but seems to give no particular advantages at low count rates.

### 4 QUALITY ASSURANCE

While RNAA is potentially capable of providing analytical results without bias and with known uncertainty, the method clearly requires no less skill and experience than other methods. Quality assurance is therefore a sine qua non, and fortunately the method is particularly well suited for modern methods of quality control/quality assurance (QC/QA) based on the so-called BIPM (Bureau International des Poids et Mesures) philosophy.⁴²
The implementation of this line of thought is described in a basic ISO (International Organization for Standardization) document,\textsuperscript{43} and for use in analytical chemistry in a Eurachem Guide;\textsuperscript{44} none of these documents, however, provide any guidance with respect to RNAA or to activation analysis in general.

4.1 Statistical Control

The analytical method is in a state of statistical control when its known sources of variation fully account for the observed variability among replicate determinations.

The \textit{a posteriori} variability of \( n \) replicate analyses is expressed as the variance \( s^2 \) of results \( y_i \) in Equation (9)

\[
s^2 = \frac{\sum_{i=1}^{n} (y_i - y_0)^2}{n - 1} \tag{9}
\]

where \( y_0 \) is their mean value.

When the analytical method is completely defined, it is possible to identify and evaluate all sources of variation by statistical or other methods, referred to as uncertainty components of type A or B.\textsuperscript{45} Their influence on the analytical results is calculated by the law of error propagation on the basis of variances \( \sigma_i^2 \) of \( p \) individual components \( x_i \) (Equation 10)

\[
\sigma_0^2 = \sum_{i=1}^{p} \left( \frac{\partial y}{\partial x_i} \right)^2 \sigma_i^2 \tag{10}
\]

This resulting variability may be calculated without actually carrying out any analyses and is therefore referred to as the \textit{a priori precision}.\textsuperscript{45}

In RNAA and other methods where the process of counting stochastic events is part of the analytical method the statistics of counting has to be compounded with the \textit{a priori precision}, even though its contribution is not known until an actual measurement has been carried out. The calculation of \textit{counting statistics} is based on the Poisson distribution for the number of counts detected from a radioactive source, and this assumption has been amply demonstrated to be fulfilled in neutron activation analysis. Each photopeak area is associated with a standard
deviation, $\sigma_C$, calculated from the same spectrum and by the same computer program. The total expected a priori variability of radioanalytical results then becomes Equation (11)

$$\tilde{\sigma}^2 = \tilde{\sigma}_0^2 + \sigma_C^2$$  \hspace{1cm} (11)

where $\sigma_C^2$ expresses the contribution from counting statistics.

Agreement between a priori and a posteriori variability means that the analytical method is in a state of statistical control; this is tested by calculating the statistic $T$ by Equation (12)

$$T = \sum_{i=1}^{n} \frac{(y_i - \tilde{\mu})^2}{\tilde{\sigma}_i^2}$$  \hspace{1cm} (12)

where $\tilde{\mu}$ is calculated by Equation (13)

$$\tilde{\mu} = \frac{\sum_{i=1}^{n} y_i \tilde{\sigma}_i^{-2}}{\sum_{i=1}^{n} \tilde{\sigma}_i^{-2}}$$  \hspace{1cm} (13)

as the weighted mean of $n$ observations. If there is no significant difference between the expected—a priori—and the actual—a posteriori—standard deviations the statistic $T$ is closely approximated by a $\chi^2$-distribution with $n - 1$ degrees of freedom.\(^{(46)}\) Significant deviations from this distribution show that there is a disagreement between the sources of variability expected to influence the result according to Equation (11) and the observed variability. The process of identifying the sources and magnitudes of variability that influence the actual analytical results is called the Analysis of Precision.\(^{(47)}\)

### 4.2 Verification Methods

Verification means to verify the absence of errors, and the analysis of precision is an important tool for ascertaining the absence of unknown sources of variability. It is also possible to use this statistic to demonstrate the absence of systematic errors.\(^{(48)}\)

The most important condition for relying on the analysis of precision is that the standard deviations $\sigma_i$ of the analytical results are correctly estimated for each individual measurement. Hence, it must be ascertained that the program used to calculate the results and its associated uncertainty correctly takes into account the contributions from counting statistics and other known uncertainty components. This was tested by a series of experiments involving replicate activation and counting of identical samples under a variety of conditions, covering the entire field of potential application.\(^{(28)}\)

\(^{a}\) SEM = Standard error of the mean = Standard deviation/$\sqrt{n}$.

As an example it was considered necessary to ascertain that counting statistics were correctly calculated for spectra recorded with different gains, which means that identical photopeaks had different widths expressed as FWHM. By counting the same \(^{152}\)Eu source up to 30 times at different gain settings and using the most intense $\gamma$-line at 122 keV as a comparator the results shown in Table 6 were obtained. For each set of photopeak areas and associated counting statistics, $\sigma_C$, the statistic $T$ was calculated in accordance with Equations (12) and (13). All photopeak areas covering an intensity range of two orders of magnitude and values of FWHM from 2.8 to 15 channels were found to be in good statistical control with the possible exception of the 344 keV photopeak. This photopeak offers the highest precision next to the comparator peak and is therefore providing the highest sensitivity for the detection of unexpected sources of variability; however, no correlation with FWHM could be observed and it was therefore concluded that, although there might be a small additional random source of variation, there was no systematic effect associated with the changes in photopeak width.

Once it has been verified that all known sources of variation are correctly accounted for in the calculated standard uncertainty of the analytical result, it becomes possible to detect and identify unknown sources of variability by judicious use of the analysis of precision.\(^{(47)}\) Verification of the absence of unknown sources of variability in the analytical results, however, does not exclude the presence of a constant bias or proportional error. Only comparison with results obtained by independent methods or the analysis of materials with known composition can be used for such verification.
The preferred way of verifying the absence of such errors is to analyze a series of matrix-matched reference materials with certified concentrations of the determinand for the entire range of concentrations of interest. Results of such a verification analysis for selenium by INAA and RNAA are shown in Table 7 giving results for seven biological reference materials certified by BCR and covering a concentration range of more than two decades. On the assumption that the confidence intervals for the certified values represent the standard uncertainty with a coverage factor of 2, we can combine the uncertainties with the standard uncertainties for the actual results. The ratios between the observed and the expected results are calculated together with their associated standard deviations and presented in the last column of Table 7.

The weighted mean of these ratios is calculated according to Equation (13) and the distribution of the results is tested by the test from Equation (12). In this case the test shows no disagreement with the expected ratio of one, and therefore no detectable systematic error. Within the range of concentrations and matrices investigated we can therefore disregard blank or contamination problems, as well as interference or calibration errors.

### 4.3 Traceability Chain

Traceability is characterized by an unbroken chain of comparisons that relates the analytical result to a national or international realization of the appropriate SI units. Each step of the traceability chain must be associated with an expression of uncertainty in accordance with the ISO document, so that the combined uncertainty of the analytical result can take this into account.

Traceability is not so difficult to establish in the physical measurement of a property of a particular sample, including elemental analysis by INAA. Traceability in chemical analysis is much more complicated for two reasons:

- The traceability chain is broken as soon as a chemical separation takes its beginning, i.e. already at the sample dissolution stage.
- There are a huge number of chemical species that may require determination, some being unavailable in pure condition.

In this respect RNAA is superior to other analytical methods in keeping the traceability chain unbroken because:

- carrier addition and equilibration take place right from the dissolution stage, thereby restoring the traceability chain by the determination of the recovery of added carrier;
- the number of elements that can be determined by RNAA is not more than approximately 70; the majority of these can be used directly as comparators in the form of pure elements or compounds with known stoichiometry.

It must, however, be remembered that RNAA determines a particular isotope of the element to be determined and therefore relates directly only to the same isotope in the comparator. Thus, the indicator radionuclide represents the element as such only if the isotopic composition of the comparator exactly equals that in the sample. For the most sensitive elements listed in Table 1 this condition is essentially always fulfilled; but in special cases the isotopic traceability becomes of major concern.

Neutron activation analysis was for example used for the determination of the specific activity of $^{125}$I and $^{129}$I using $^{126}$I, $^{128}$I, and $^{130}$I as indicators. In this case total iodine content had a completely different isotopic composition from naturally occurring iodine and could

only be determined by using individual comparators for all nuclides, each having its own traceability chain.

The uncertainty with which a result can be reported is thus limited by the uncertainty of the traceability chain, which should therefore be kept at a level where its contribution is small in comparison with other uncertainty components. This is usually achieved by the use of certified reference materials from internationally recognized sources like BCR or NIST (National Institute of Standards and Technology).

In a method like RNAA with inherently small uncertainties and a short traceability chain the contribution to the uncertainty from the traceability chain can be kept at a level of less than 1% when several different pure isotopic comparators are used.\(^{(52)}\) The use of the so-called \( k_0 \) method\(^{(53)}\) based on the use of comparators of elements different from the determinand also represents a break in the traceability chain and is therefore discouraged in the context of using RNAA for certification purposes.

### 4.4 Uncertainty Budget

When standard deviations, \( \sigma_i \), have been estimated for all uncertainty components, \( p \), discussed in section 2, the uncertainty budget is composed simply by listing the individual items of the summation in Equation (10). Common to all RNAA budgets are sample weight, quantity of comparator, half-life of indicator, neutron flux density variation, measurements of decay and counting times, amount of carrier, and recovery. Another important common feature is that the radiochemical separation as such does not contribute to the uncertainty in any other way than expressed by the recovery, which means that the entire a priori standard uncertainty is independent of the concentration of the determinand.

All these major uncertainty components are evaluated by statistical methods and therefore belong to Type A.\(^{(43)}\) Other uncertainty components may have to be evaluated by inference from other methods or by previous experience; such contributions are referred to as Type B. In RNAA, uncertainty components of Type B might include several potential losses or gains of determinand or comparator that are not otherwise accounted for, such as:

- sample contamination before or during irradiation
- loss of determinand before complete carrier equilibration
- leaching from or adsorption to the irradiation container walls
- influence of moisture etc. on sample weight
- effects of radiolysis
- incomplete sample dissolution.

Many of these uncertainty components apply to both sample and comparator, and estimated corrections should in principle be applied to the results of the analysis. The comparator should have a much higher concentration of determinand than the sample and therefore be much less susceptible to contamination than the sample, but losses might occur from:

- incomplete transfer from the irradiation container
- diffusion, adsorption, or precipitation during irradiation.

The experienced analyst should be able to reduce the magnitude of all these effects to the extent that even with an estimated Type B combined standard uncertainty of 100% of the correction to be applied, there would be no significant influence on the uncertainty budget.

In a budget for the determination of chlorine by RNAA\(^{(48)}\) all Type A contributions are listed with their individual standard uncertainties, as shown in Table 8. Based on the analysis of precision and the application of the \( T \)-statistic from Equation (12) it had been concluded that no detectable contribution from Type B uncertainty components could be detected.

Since RNAA is characterized by the absence of reagent blanks the uncertainty budget contains only relative sources of variation, which facilitates the comparison of the items: it is here immediately recognized that the variation in fluence between sample and comparator is the main contributor to the combined uncertainty, whereas weighings have no detectable effect. The influence of half-life depends entirely on the time lapse between the measurement of the separated sample and the comparator. In this particular case the recovery is determined by re-irradiation, which means that the contributors from its measurement are exactly the same as for the sample itself.

Even in a complicated method like RNAA the combined uncertainty is almost always dominated by one or two uncertainty components, one of which is often the contribution from counting statistics. As pointed out above, this contribution is not known until an actual analysis has been carried out; therefore it does not strictly

belong to the a priori precision, but must of course be included in the combined uncertainty.

At very low levels of the determinand the a priori precision becomes insignificant, and the uncertainty is completely attributed to the counting statistics; this contribution can be influenced by the choice of detector, counting geometry and counting time, thereby making an a priori estimation less meaningful.

4.5 Statement of Uncertainty

Results presented without uncertainty are useless because no conclusions can be based on them; results with incorrect uncertainty are dangerous because false and misleading conclusions may be drawn.

The tradition of quoting only uncertainty from counting statistics when reporting results obtained by neutron activation analysis is therefore dangerous and should be supplemented with the a priori precision obtained from the uncertainty budget.

Both the analytical result and its uncertainty must be given in SI units with the appropriate subdivisions, and it is preferable to state the standard uncertainty, so that statistical tests and inferences can be made directly from the numbers presented. This applies to all results, including those that are not significantly different from zero, or even negative numbers.

As an example we shall take the numbers for platinum in radiochemically separated samples of BCR 186 that were presented in Table 4. These numbers are typical for analytical results, obtained as a difference between two almost equally large numbers: without any real difference between these numbers the probability of getting positive or negative results is the same, and getting three negative and one positive result from four experiments as in this case, has a probability of 25%. The quoted standard uncertainties confirm that the individual numbers are not significantly different from zero.

Thus, there is no reason to regard these numbers as in any way suspicious and therefore they should also be treated in exactly the same way as all other results. Concentrations are calculated exactly as usual, and results are presented in Table 9 together with their uncertainties. Application of the T-test from Equation (12) shows no significant difference between the results, which can therefore be pooled in accordance with Equation (13). The final result is closer to zero than any of the individual results and its standard uncertainty is smaller.

The standard uncertainty provides a confidence interval corresponding to approximately 67% for a normal distribution and this changes very little with deviations from this distribution. However, in many practical situations this confidence interval is not generally appreciated, and it has been decided to multiply the standard uncertainty with a coverage factor, \( k \), which is frequently taken to be a factor of 2. This gives a coverage of 95% for a normal distribution, but this number may change considerably with deviations from this assumption. Under all circumstances the coverage factor must be reported for all analytical results, so that standard uncertainties can be recalculated before use of the data.

Instead of reporting negative results or results with large uncertainties some laboratories prefer to present their results simply as n.d. (not detected). In other cases, compliance with legal requirements or limits necessitates reporting safe upper limits, which are conventionally set as three times the standard uncertainty. Such deflation of the information content is, however, strongly discouraged and should always be accompanied by the reporting of the original data, positive or negative, with their associated standard uncertainty.

Proper reporting of analytical results makes possible the direct application of the analysis of precision and other statistical tools to help in deciding whether a difference between sets of measurement has been observed or not and thereby helps to avoid drawing false conclusions.

5 PERSPECTIVE AND FUTURE DEVELOPMENTS

A top priority in the analytical perspective is the introduction of the BIPM philosophy in analytical chemistry courses at the university level and the implementation of the corresponding ISO Norm at the practical level, so that analytical results can assume their rightful place in the hierarchy of measurement science. This process has been hindered by the traditionally inexact and ambiguous chemical terminology, and the pontification of incommensurate terms and concepts in some ISO standards. Publication of the EURACHEM guide has been a
very significant step forward, but its recommendations are not yet mandatory even for laboratories seeking accreditation. The methodology of RNAA has contributed significantly to revealing such inadequacies and continues to pioneer the introduction of generally recognized measurement concepts and definitions in analytical chemistry.

5.1 Analytical Metrology

The purpose of analytical metrology is the introduction and implementation of metrology in analysis, based on the successful use of the BIPM philosophy in physical measurements, which at any rate are assuming a dominant position in contemporary analysis. In metrology we require correction for all known errors before reporting a measurement, while the uncertainty of the correction must be included in the uncertainty budget. This is often neglected in analytical measurement, where even corrections for blank value or recovery are not always made.

This has been brought out very clearly by comparisons between traditional chemical analyses and purely instrumental methods, where the latter frequently yields higher results for the content of trace elements or other determinands, because of incomplete dissolution of the sample or loss of elements. At the lowest levels this has sometimes been compensated by the inadvertent contamination of the sample during chemical processing or inadequate blank correction.

Correction for incomplete recovery that can always be made in RNAA by measurement of the chemical yield of the carrier is much less straightforward in alternative methods, but nevertheless has to be done during the development stage of the analytical method by using radioactive or stable tracers.

Correction for incomplete sample dissolution can be made by separate analysis of the solid residue by an instrumental method such as INAA.

If such corrections are small their contribution to the uncertainty budget is also small and may be based on sound judgement as a Type B component to the combined uncertainty.

5.2 Certification Analysis

The certification of reference materials for elemental content is required for purposes of international traceability and the mutual recognition of laboratory accreditation needed in environmental and commercial activities. No effort is spared by the leading suppliers of CRMs to make sure that the certified concentrations are reliable, and each of them have developed procedures for performing certification analyses that minimize the risk of erroneous or misleading certification.

The aim is to certify the total amount of an element present in the material, regardless of its chemical or physical form, and the certified value should be as close as possible to the true value, which means that corrections must be made for all known or assumed biases. In order to minimize the risk of overlooking unknown or unexpected biases, the use of several independent analytical methods for determining the same element is the basis for all serious certifications.

The absence of a reagent blank, the possibility of determining the recovery of added carrier, and the maintenance of statistical control make neutron activation analysis very attractive for the certification of low concentrations of the elements listed in Table 1. Together with its direct traceability to the pure element this makes neutron activation analysis a potentially definitive method.

The combination of RNAA with INAA using different indicators and different comparators even opens up the possibility of self-validation by fulfilling most of the requirements for completely independent methods of analysis. This introduces the possibility of certifying reference materials for elements for which no alternative reliable methods are available.

These properties of RNAA further emphasize the applicability of this method for certification purposes, and Table 10 presents examples of elements determined in a variety of reference materials, certified by BCR and covering the entire range of trace element concentrations from 0.01 mg kg$^{-1}$ to 0.01%. Particularly since the introduction of natural materials for certification, NIST and all other major suppliers have counted on neutron activation analysis not only for elements with

</table>

Form of a minimum sample size or – preferably – as a statement of the maximum sampling constant. All reference materials are carefully homogenized during their preparation, which means that they may be considered uniform and therefore can be characterized by the Ingamells’ sampling constant (Equation 14)

\[
K_S = R^2 W
\]  

where \( R \) is the coefficient of variation observed by the analysis of replicate samples with weight \( W \). With a known sampling constant the contribution of heterogeneity to the variability of results is accounted for by adding a term to the a priori precision from Equation (11) (Equation 15)

\[
\hat{\sigma}_W^2 = \sigma^2 + \frac{\mu^2 K_S}{10^4 W}
\]

which also shows that the sampling constant can be determined by analyzing a number of samples by an analytical method in statistical control.

Present reference materials have sampling constants of the order of 1 g but modern methods of analysis use much smaller samples and therefore need materials with smaller sampling constants. Sampling constants need to be determined separately for each determinand, and the use of methods that are in statistical control regardless of sample size is therefore in great demand. For many elements both RNAA and INAA can be used on samples in the milligram to microgram range without problems and therefore can be used to advantage in future verification of very small sampling constants just by activating the samples in very high neutron flux densities.

Radiochemical activation analysis is a more laborious analytical method than instrumental analysis, but can be used to determine elements at lower concentrations. In most cases, the sample to be analyzed is separated into groups of elements rather than individual elements, so that the elements do not interfere with one another during the measurement of radionuclides content. Schemes for separation into multielement groups are given for metals, biological, geological and environmental samples.

1 INTRODUCTION

While instrumental neutron activation analysis (INAA) is more popular than RNAA (radiochemical neutron activation analysis), owing to its simplicity, RNAA can determine much lower concentrations than INAA, because the interferences from other radionuclides are reduced considerably. Whereas INAA involves only activation and activity measurement, RNAA also includes dissolution of the sample and chemical separation of the sample solution. In some cases, the interferences can be removed by decay (“cooling”) and INAA can be used. However, in many cases the IRNs (indicator radionuclides) are shorter lived than those of the interferences, and in other cases the required decay time is too long to be practical. Owing to the chemical dissolution, separation and recovery yield determination, RNAA involves more person hours and should be avoided when it is possible. Heydorn, in his article Radiochemical Neutron Activation Analysis, shows why RNAA is so important in verification of the concentration of trace elements in reference materials. However, RNAA is not just used for validation of reference materials, although this is clearly one of its main uses. RNAA involves irradiation and counting, dealt with in the article Instrumental Neutron Activation Analysis, as well as dissolution of the samples and separation of the dissolved samples into various groups. The dissolution step is much simpler than for other methods of analysis, because the final measurement is the determination of the radionuclides formed by the irradiation. As the dissolution step is done after the irradiation is carried out, no contamination during the dissolution step can influence the final results. In addition, as the dissolution of the sample is done together with that of carriers, the danger of losing trace elements by adsorption is considerably lower. On the other hand, owing to the radioactivity of the irradiated sample, the dissolution, if performed many times, should be done behind lead shields. In principle every chemical separation that is used in any other analytical method can be used in RNAA. But since the separation very rarely involves a single element, an appropriate group of elements which do not interfere with each other is different for various determination methods. This is the reason that it was decided that it was worth collecting together in this article the main methods of chemical separation into groups that are used in RNAA. In some cases, even the separation into groups is not needed, and it is sufficient to remove the major interferences. Egger and Krivan in their determination of trace elements in aluminum, removed only the interference of $^{24}\text{Na}$ (by sorption on a hydrated antimony pentoxide, HAP, column) and were then able to measure 38 trace elements, all in concentrations of less than 1 ppb. For most other analytical methods the bulk of Al might need to be removed.

An additional aspect which is different for RNAA with respect to all other determination methods, is that in RNAA the final determination can be performed while the trace elements are adsorbed onto a separation column, whereas all other methods require the elution of the trace elements from the column.

2 SEPARATION IN MATERIAL SCIENCES

Park et al. studied the concentration of 13 trace elements in high-purity molybdenum by separating them into three groups, separated from the major interferences which are Mo and W. A cation exchange column (Dowex™ 50) in dilute HCl medium is used to remove Mo and W, which are only weakly adsorbed on this column, while many of the impurity elements are strongly absorbed. Na and K are eluted by using additional dilute
NUCLEAR METHODS

**Figure 1** Park et al.\(^2\) method for separation of 13 elements into three groups for determination of trace elements in molybdenum. (Reproduced from Park et al.\(^2\) with permission.)

Mo and W were digested and heated to dryness. Then, they were digested with 30 mL 1% H\(_2\)O\(_2\) and passed through a Dowex™ 50X8 column. The eluate was concentrated by partial evaporation.

Np and Pa were separated from Mo and W using anion exchange (Dowex™-1) in strong nitric acid media. Pa and Np are strongly absorbed on the anion exchange resin, while molybdenum and tungsten are not. Figure 1 gives a schematic representation of the process of separation of Park et al.\(^2\). Before counting, each eluate was concentrated by partial evaporation.

Theimer and Krivan\(^3\) developed a group separation for the determination of 20 elements in high-purity molybdenum (Figure 2). They developed two modifications. The first one involves removal of Mo and its daughter Tc and the main contamination of W, by absorption on anion exchange resin (Dowex™ 1X8). Five other elements are also absorbed on the column, but 20 elements are eluted and can be determined simultaneously in the eluate. The second modification allows determination of only 11 elements, although separation is effected into two groups. The advantage of this special modification is the separation of \(^{233}\)Pa (the IRN of Th) with only Sc, enabling determination of small amounts of Th. Both modifications are based on elution with various concentrations of HF, similar to all the procedures developed by Krivan et al. for determination of trace elements in metals. The flow chart for the two radiochemical separation procedures is given in Figure 2. The two methods are based on Mo, Tc, and W being absorbed on an anion exchange column in HF media, while the trace elements are eluted with HF. For selective separation of Pa (together with Sc only), lower concentrations of HF are used. The elements given in parentheses are eluted but not completely, so that they are found both on the column and in the eluate. The elements determined via medium-lived IRNs and which had...
Figure 3 Flow chart for the radiochemical separation of trace elements in tungsten. (Reproduced from Caletka et al.\(^4\) with permission.)

to be in eluate 1 according to their distribution ratios, as for example Cu, Ga, K, Mn and Na, do not appear in procedure B, because about 1% of the technetium is eluted with this fraction, masking the activity of these IRNs. However, if (NH\(_4\))\(_2\)S\(_2\)O\(_8\) is added to the sample solution prior to its evaporation, in order to oxidize all technetium species to the heptavalent state, less than 0.01% of the technetium is found in fraction 1, and the other elements can also be determined in this fraction.

A similar technique was developed by Krivan’s group to determine the content of 19 elements in high-purity tungsten.\(^4\) However, a modification was done in order to measure the concentrations of Ta and Sb, which in the previous processes were adsorbed on the anion exchange resins together with Mo, Tc and W, and could not be determined. Ta and Sb are extracted with organic solvent (dichloroethane, DCE) after forming complexes with diantipyrilmethane (DAM), prior to the introduction of the solution of the dissolved irradiated tungsten onto the anion exchange column. In order to measure the P content via \(^{32}\)P, a \(\beta\)-only emitter, \(^{32}\)P is substoichiometrically extracted as molybdophosphate with tetraphenylarsonium chloride in dichloromethane.\(^5\) The flow chart for this separation is given in Figure 3.

Figure 4 Two procedures for RNAA of trace elements in niobium (a) for medium-lived IRNs; (b) for long-lived IRNs. HDEHP, di(2-ethylhexyl)-orthophosphoric acid. (Based on figures from Caletka et al.\(^6\) with permission.)
Caletka et al. developed a RNAA procedure for determination of 26 elements in niobium by irradiation and processing of two samples, one for measurement of medium-lived IRNs (the radionuclide used for the determination of an element in NAA), by irradiation for 12 h. The second sample was irradiated for 5 days in order to determine the long-lived IRNs. In the determination of medium-lived IRNs, they wanted to measure $^{56}$Mn ($t_{1/2} = 2.58$ h) and $^{65}$Ni ($t_{1/2} = 2.52$ h) as well. This is possible because the main activity produced from the matrix ($^{94m}$Nb) is short lived ($t_{1/2} = 6.24$ min) and one hour of cooling leaves a sample that is not too radioactive to handle. For matrixes where the main activity is longer lived, IRNs with half-lives of a couple of hours can be determined only by pre-irradiation separation of the matrix, or treatment in special hot laboratories, where very high radioactivity can be handled. Different schemes of separation were devised for the medium- and long-lived IRNs, however, they have many common features. Both use solvent extractions followed by separation on columns. The same two solvent extractions were used in the two

**Figure 5** Procedure for separation of 52 elements into 10 fractions in irradiated ultrapure aluminum. (Reproduced from Egger and Krivan with permission.)
procedures, and the only difference is in the columns and acids used for separation of the last aqueous phase into three groups. The first extraction step is for cations which form chelates with dithizone and are extracted with chloroform. This fraction includes Cu, Au, Pd and Pt in the medium-lived IRNs, and Ag, Se in the long-lived IRN samples. The second extraction of metals is for those which form complexes with DAM. The organic solvent is DCE. This extraction is used to remove tantalum and niobium, and the organic phase containing them is discarded. The elements remaining in the aqueous phase are separated into three groups using two columns in series. One group is adsorbed on each column, and the third group contains the elements which were eluted from the two columns. For the long-lived samples, the first column is the reversed phase di-(2-ethylhexyl) orthophosphoric acid on a solid support which were eluted from the two columns. For the long-lived samples, the first column is the reversed phase di-(2-ethylhexyl) orthophosphoric acid on a solid support and then a column of anion exchange resin-Dowex™-1. For the medium-lived IRNs, the anion exchange-Dowex™-1 is the first column, followed by a HAP column. In high-concentration HCl solution, HAP retains only the Na ions; however, under the conditions used here, K also remained on the HAP column. The flow chart of the separation is given in Figure 4.

A thorough determination of the trace elements in ultrapure metal was performed for aluminum.(7) Previously, we mentioned that 38 elements were determined in levels of parts per billion, by selective removal of 24Na with a HAP column. Later, the same group extended this study, and in order to improve the limits of detection, an additional separation into 10 groups was done.(7) Forty-three elements have limits of detection below 10 ppb, and for U and Th the limits of detection are 50 ppt (5 x 10^-11). The separation scheme is given in Figure 5. First, Na⁺ is retained on HAP. With 12-M HCl elution, this is the only cation to be retained. The eluate from the HAP column is loaded onto an anion exchange resin-Dowex™-1X8 anion-exchanger column. The masking of anions by boric acid leads to retention of Pa and Np (IRNs of Th and U) on the column. Further elements are separated on a cation exchanger. The solution is evaporated to dryness, dissolved in 0.1-M HCl and introduced into a cation exchanger Dowex™ 50X8 and washed with 0.1-M HCl. The eluate is one group of five elements, while the 27 elements remaining on the column are separated into three groups by two elutions.

The flow chart for the separation (Figure 5) shows the separation of 52 elements as studied by radiotracers. Not all of them were found in the ultrapure Al. Only those not in brackets were actually found in the irradiated Al.

3 GEOLOGICAL AND ENVIRONMENTAL SAMPLES

Many studies have been done on the determination of precious metals in geological samples. Nadkarni and Morrison(8,9) digested the irradiated sample
(200–500 mg) by peroxide fusion, and separated the noble metals on a Srafion NMRR selective chelating ion-exchange resin. However, yields are not well reproducible and reirradiation of each sample is necessary to determine them. Only Pd, Pt, Ir and Au can be determined by this process. The use of the ion exchanger Srafion NMRR was questioned by Stockman, who could not repeat the results of Nadkarni and Morrison and attributed this to changes in the manufacture of the resin. There are also some previous data which give contrasting results for the specificity of this resin for d8 ions.

Chai et al. developed two different methods for radiochemical separation of the noble metals. They found that Nadkarni and Morrison were right and the Srafion NMRR resin can be used to retain Os and Ir. Ten milliliters of 0.05-M HCl eluted 100% of Sc, Cs, and Fe, whereas only 10% of Os was eluted. Nadkarni and Morrison reported that thiourea can be used to elute the noble metals, whereas Stockman argued that thiourea elutes only gold, while Ir remains on the resin. Chai et al. found that Ir and Re can be eluted with NH3, whereas only one-quarter of Os was eluted and no Au or Pt. Chai et al. found that all platinum group elements (PGE), including Au, are retained by various productions of this resin. Chai et al. suggested a scheme for radiochemical separation of noble metals, which is given in Figure 6. They found that their digestion process forms mainly Ir(III), which is not absorbed onto the chelate resin. However, oxidation of the chelated Ir with hot H2O2 transforms all Ir to the +4 oxidation state, which is absorbed on another column with the same resin.

An alternative process for the separation of the noble metals, suggested by Chai et al., is based on extraction of noble metals with long-chain primary amines (19–23 carbon atoms) in DCE. All the noble metals are extracted in high yields into the organic phase. The base metals were only negligibly extracted.

Another group besides the noble metals, which is determined many times by RNAA, is the rare earth elements (REE) group. Zilliacus et al. described two procedures for the separation of the REE group from irradiated geological samples. A simple and faster method was developed for samples with concentrations above 0.5 ppm, while a method with more separation steps was developed for samples with lower concentrations. A more time-consuming process is required to obtain a clean REE fraction. The two processes are described in Figure 7. Both methods are based on fusion with

![Figure 7](image-url)

*Figure 7* Separation scheme for the analysis of REE in geological samples (Reproduced from Zilliacus et al. with permission.)
Na$_2$O$_2$ and cycles of precipitation as hydroxides and as fluorides. In the simple method there is one more step for removal of Sc and other metals by extraction with tributylphosphate (TBP). For the lower concentration samples, SiO$_2$ is removed by precipitation with gelatin in acidic solution, the main interferences are adsorbed on an anion exchange column in a HCl medium, while the REE are eluted. Sc is removed by extraction with ether from SCN$^-$/NUL solution. Purification of the REE fraction is done by a cycle of precipitation of hydroxides and fluorides. A similar process was also developed by Laul et al.$^{(16)}$ They did not use the Sc removal step by extraction; however, in the final step, they performed three cycles of hydroxides–fluoride precipitation.

A similar method was developed by Wandless and Morgan.$^{(17)}$ The method is based on the precipitation of the REE hydroxides both at high pH and at pH 9 in ammoniacal solution. SiO$_2$ is removed by precipitation with gelatin in acidic solution. Fe is removed by an anion exchanger in the Cl$^-$ form from 8-M HCl solution. Zr, Sc and Hf are removed by an anion exchanger in the SCN$^-$/NUL$^-$ form from 0.8-M SCN$^-$/NULC$^-$ 0.5-M Cl$^-$/NUL solution. The only remaining interference is Cr$^{3+}$, which is removed by precipitation of the REE with excess 8-M NaOH. The complete scheme is given in Figure 8.

Parthasarathy et al.$^{(18)}$ separated the REE into two groups rather than into one group, as in all other processes. They separated a group of light REE and a group of heavy REE. The process is different from all those previously described, and the flow chart is given in Figure 9.

Morrison et al.$^{(19)}$ described a procedure for chemical group separations, which, with the use of a Compton suppression Ge(Li) detector, can determine 45 elements in geological samples. The flow chart for this process is given in Figure 10. The first group is the one including volatile elements and volatile fluorides. Elements adsorbed to HAP in 8-M HCl formed the second group. Those adsorbed to anion exchange resin in 8-M HCl formed the third and fourth groups. The separation between these two groups is done by elution with 0.5-M HCl. The elements not adsorbed on the anion exchange in the 8-M HCl are separated into two groups by extraction with TBP. Laul et al.$^{(20)}$ developed a RNAA method for trace elements in terrestrial rocks and stony meteorites. They stated that their main emphasis was to minimize chemical procedure and maximize the γ-ray spectrometry aspect. However, their separation is longer than that of Morrison et al.$^{(19)}$ and they measure only 16 elements. The flow chart of their separation is given in Figure 11. The scheme involves four different separation techniques: distillation, solvent extraction, ion-exchange columns, and precipitation.

Smets et al.$^{(21)}$ developed a group separation for RNAA determination of 24 elements in a wide variety of silicate rocks and minerals. The samples were decomposed in a HF–HNO$_3$ mixture in a PTFE (polytetrafluoroethylene) lined bomb, and were separated into soluble and insoluble fluorides. The soluble fluorides were separated into three groups by sequential elution (0.1-M HF, 3-M HCl + acetone, 12-M HCl) from a cation exchange column. The insoluble fluorides (Ca, Sr, Ba, REE and part of Rb and Cs) were dissolved and purified from iron and scandium activities by extraction with TBP. The separation scheme is given in Figure 12. The elements written in large type were determined, whereas those elements in small

type are found in more than one fraction and cannot be determined. In some samples their concentration is too high and they might interfere with the determination of the other elements in the group. For these cases, the authors developed a more thorough scheme, in which for each fraction there is a method of removing the interference. However, these further steps should be done only if $\gamma$-spectrometry will not be sufficient.

Pietra et al.$^{22}$ developed 22 different RNAA procedures for environmental and biological samples. Many of these procedures are for several elements or for single elements; however, some are for group separations. The most extensive procedure (50 elements) was used only for biological samples. The next most extensive (39 elements) procedure was used for geological samples, and the separation scheme is depicted in Figure 13. The samples were dissolved in acid mixtures in a Teflon bomb, and, after drying, dissolved in 0.1-M HNO$_3$ which was also used as the only eluant. The trace elements were separated into five groups by the use of five different columns: acidic aluminum oxide (AAO), tin dioxide (TDO), copper sulfide (CuS), cadmium oxide (CdO) and HAP. The separation time for this procedure is about 2 h. All the IRNs were counted in the columns without elution. In another scheme where the geological material was dissolved in 6-M HF, the HAP column was used first, followed by the cation exchange column, and later an anion exchange column can be used to separate the mixture into four groups in which 35 elements can be determined. As in the previous scheme, in order to simplify the procedure and to make it easier for automation, only one eluant (6-M HF) is used.

Vasconcellos and Lima$^{23}$ developed a procedure that is between several elements and a group separation. It is based on the use of three columns: HAP, anionic resin column and a reverse phase chromatography column with TBP on a Kieselguhr support. Several elements appeared in more than one fraction, but all the REE appear in one group and can be measured. As in the previous scheme, in order to simplify the procedure and to make it easier for automation, only one eluant (6-M HF) is used.

4 BIOLOGICAL SAMPLES

Many group separations were developed for biological materials. Some of them divide the sample into a few groups measured on a Ge(Li) or HPGe detector, while others perform very elaborate separations into many groups to enable activity measurements on very small amounts using a well-type NaI(Tl) detector. Figure 15 shows the flow chart of the Pietra et al. procedure for the determination of 50 elements. The procedure starts with distillation of the elements (Cl, Br, I, Os) and the chlorides–bromides (Sb, Sn, Hg, Au, As, Se, Ge, Re, Ru). The chlorides–bromides are separated into six groups (not more than two elements in the same group) by the use of two columns (first an anion exchanger and then TDO) with successive elutions. An arrow from the column means elution. Elements with arrows to the column are retained on the column. Elements in brackets are present in more than one group. The nonvolatile elements/chlorides/bromides are separated using successive elutions with six columns: anion exchanger, CuS, TDO, AAO, and cation exchanger. The procedure of Pietra et al. for the determination of 39 elements using five columns with a single eluant, which is described for geological material, was also used for biological material (Figure 13).

Although 50 elements can be separated and determined, most studies do not need so much information, and most studies measured 10–20 elements by more simple methods. Pietra et al. have several schemes for this purpose. van Renterghem and Cornelis determined 10 elements in human serum. Their procedure divides 13 elements (Na, K, and Br were not determined in the serum) into three groups by using an anion exchange column in the Br⁻ form with two elutions. The scheme is shown in Figure 16.

Sixteen trace elements were determined by the same group using three columns and one eluant as can be seen in Figure 17.

Schuhmacher et al. developed an almost complete scheme, in order to enable the activities to be measured with a well-type NaI(Tl) detector, to measure the contents of 25 trace elements in small biological samples (1–15 mg). The scheme is based on 14 consecutive columns divided into three Groups (3,7,4). For all columns in one group, the same eluant was used. Between the second and third group the eluate is automatically titrated to pH 2. The scheme is shown in Figure 18.

Figure 19 gives the scheme of Yeh et al. for group separation, measuring 21 elements, not including Na and Br, which can also be measured. This scheme includes distillation of Br as an element, a HAP column, As and Se distillation as bromides, and an AAO column. A more extensive review on RNAA can be found in Alfassi.

Small amounts of radionuclides of suitable half-life can be used to observe the kinetics of mass transport and isotopic exchange in the equilibrium distribution of a (micro-)component between coexistent phases. Quantitative assay of radioactivity is sensitive, precise and accurate and usually performed instrumentally. Though handling of radionuclides is restricted to authorized laboratories only, the combination of its potential and simplicity makes the radiotracer method an indispensable part of modern analytical chemistry.

1 INTRODUCTION

Small changes in isotopic composition by addition of minute quantities of either stable isotopes or radionuclides offers the possibility of labeling ions and molecules without significant shifts in their thermodynamic properties. This “tracer” principle enables the observation of kinetics, including isotopic exchange and equilibrium distributions.

The measurement of stable tracers is performed by mass spectrometry, usually on small aliquots of solution. As a rule, assay of radiotracers may be achieved by direct \( \beta \) or \( \gamma \) counting of relatively large subsamples. In case of \( \alpha \)-active radiotracers, sample pretreatment is mandatory to obtain a thin-layered counting aliquot.

Radiotracers are applied in authorized laboratories only. Owing to the sensitivity of detection, the amount of activity, expressed in disintegrations per second per Becquerel (Bq) can be at quite a modest rate, usually below \( 10^5 \) Bq. Such quantities can be handled with simple precautions in the many low-level tracer laboratories in hospitals, industry and university laboratories.

The most frequent application of the method is in medical diagnosis, followed by metabolic studies, environmental transport and availability experiments, including pilot plant simulations. The optimization of benchtop analytical procedures constitutes another established range of uses. This text concentrates on the principles of the radiotracer method and its nonmedical applications. A few illustrative cases have been taken from environmental studies, material science and analytical procedure development.

2 PRINCIPLE AND FORMULATION

2.1 General

The basic idea of the radiotracer method is the supposed identical behavior of stable and radioactive nuclides. Thus the presence of a tiny amount of an isotopic radionuclide, negligible in weight but well able to be detected by its radiation, enables observation of the “labeled” element. The chemical species of the radiotracer should be equal to that of the bulk mass in question. Thus both ions and (labeled organic) molecules are used. The small influence of the mass difference can be neglected in the large majority of applications. It becomes significant for light elements only, from about oxygen to elements of lower atomic mass, and in some artificial arrangements for isotope separation.

The signal obtained from a radiotracer depends on the concentration and the specific activity of the compound or phase which is being measured. In the case of a closed system, a radiotracer experiment gives information on the rate of the net mass-transport which affects the concentration, and on the rate of isotopic exchange which...
influences the specific activity of the compound of interest. In open systems this distinction is not generally made but the variation of the signal is considered to be proportional to the changes in concentration.

2.2 Radiotracer Experiments in Closed Systems

The aim of radiotracer experiments in closed systems is to observe the interaction between two or more phases and compounds and, eventually, their equilibrium situation. Usually an amount of radioactivity is added as a component of one phase or compound and its quantity measured as a function of time. If the reaction between two compounds in one phase is examined, separation has to be performed prior to the measurement. Often an aliquot is taken for counting.

The result is a number of counts, \( A \), related to the specific activity, \( a \) (disintegrations s\(^{-1}\) g\(^{-1}\) or disintegrations s\(^{-1}\) mol\(^{-1}\)) and the concentration, \( c \) (g L\(^{-1}\) or M) by Equation (1)

\[
A = \gamma ac
\]

The constant of proportionality, \( \gamma \) (in counts disintegration\(^{-1}\) s L or counts disintegrations\(^{-1}\) s mol), accounts for the volume of the aliquot and the counting conditions. At the beginning of the experiment Equation (2) follows

\[
A_0 = \gamma a_0 c_0
\]

and thus, Equation (3)

\[
\frac{A}{A_0} = \frac{a}{a_0} \frac{c}{c_0}
\]

If we now write Equation (4)

\[
f_A = \frac{A}{A_0}, \quad f_a = \frac{a}{a_0} \quad \text{and} \quad f_c = \frac{c}{c_0}
\]

it follows that Equation (5)

\[
f_A = f_a f_c
\]

and thus, with \( \frac{df}{dt} = f' \), Equation (6)

\[
f'_A = f'_af_c + f'_f
\]

Equation (6), the activity balance, together with the mass balance, forms the basis of all radiotracer experiments in a closed system. In kinetic studies the third obvious equation is the rate balance: at equilibrium the net rate of two opposing reactions must be zero.

Without net mass transport \( f_c = 1 \) and \( f'_c = 0 \) and thus \( f'_A = f'_a \) and \( f_A = f_a \). In this case, a gradual isotopic exchange can be observed. If on the other hand there is no isotopic exchange, the reverse holds and \( f_A = f_c \), enabling the measurement of net mass transport.

When both \( a \) and \( c \) change during the experiment, extra information is needed to solve Equation (6). This may take the form of a separate determination of \( f_a \) or a logical prediction of \( f_c \). The various possibilities are summarized in Figure 1.

A clear distinction must be made between the amount of radiotracer which is present in the system and that which is available: in leaching experiments on radioactivated solids the available amount increases nonlinearly with time.

In general, the moment of introduction of the radioactivity does not coincide with the beginning of the

![Figure 1](image-url)  
**Figure 1** Survey of radiotracer experiments in a closed system.
interaction. By varying that moment, a (decreasing) ratio between net mass transfer and isotopic exchange may be observed.

Applications of radiotracer experiments to closed systems refer to interactions between compounds in one phase or different, adjacent, phases. As isotopic exchange or net mass transfer may be requested, this makes four possible combinations.

2.2.1 Isotopic Exchange

Generally, the reaction is of the type \( AB + A^*C \leftrightarrow A^*B + AC \). The asterisk indicates the radiotracer. By definition, the time of its introduction is taken as zero. By plotting the logarithm of the exchanged fraction against time, the rate constant can be obtained. A similar formalism is applicable to isotopic exchange between two adjacent phases.

2.2.2 Net Mass Transport and Final Spatial Distribution

The case of net mass transport at a constant specific activity is by far the most frequent among radiotracer applications. A complication arises when the total available amount of radioactivity changes with time, as in the leaching of radioactivated or labeled solids. The activity of the leachant is measured as a function of time. It is obvious that the specific activity will remain constant only when the fresh eluent does not contain this element of interest. The mass balance may be written as Equation (7)

\[
V \frac{dc}{dt} = GF(t)
\]

where \( V \) is the volume of eluent (mL), \( c \) is the concentration in the eluent (g mL\(^{-1}\)), \( t \) is the time (h), \( G \) is the amount of solid (g) and \( F(t) \) is the specific mass transfer function (g g\(^{-1}\) h\(^{-1}\)). Measurements of \( c \) as a function of \( t \) yields \( F(t) \).

Table 1 gives the empirical expression for \( F(t) \) and those for \( f_A \), the number of counts as a function of time for a leachant without or with some initial concentration of the analyte.

2.3 Radiotracer Experiments in Open Systems

Radiotracers are used in open environmental systems to measure flow rate and/or time of residence as well as their distributions. This is invariably done by a one-time (\( \delta \)-function) injection. Either the radioactivity is added to the system or induced by activation in small aliquots taken from the system. Unlike experiments in a closed system, \( f_c \) only is considered. Thus \( f_A = 1 \) and \( f_A = f_c \), implying that the radiotracer remains in its original phase.

In principle, there are no special rules involved in the use of a radiotracer as the tagging agent. Thus the formalism developed by Danckwerts\(^{(4)}\) and expanded in many textbooks, like that of Levenspiel,\(^{(5)}\) may be used. The distribution of the radiotracer over the effluent, \( f(t) \), is determined. From this the first and the second moment, average residence time and its variance are calculated. These measurements are mandatory in column leaching studies as the flow pattern influences the activity elution curve.

2.4 Limitations of Radiotracer Methods

Applications of radiotracers are restricted by fundamental as well as practical reasons. The limited choice of radiotracers and their half-lives and the isotope effects in reaction rates and equilibrium concentrations can be regarded as fundamental restrictions. The requirements for the operation of a radiochemical laboratory and the mandatory safety precautions in field experiments are of a practical nature.

The finite number of useful radionuclides and the limitations in their availability are reflected by any commercial catalogue. The most important consequence is the predominance of \( \beta \)-counting, usually by liquid scintillation, in physiological tracer experiments.

The influence of the mass difference between the natural isotopic mixture and the radiotracer can be expressed in terms of empirically determined correction factors for equilibria and reaction rates.\(^{(6,7)}\) In elements with atomic masses greater than oxygen, the effect is usually lower than 5%.

2.5 Practical Applications of Radiotracers

The numerous applications of radiotracers can be systematized by division into three broad categories:

- optimization and performance of laboratory determinations by chemical separation
- measurement of spatial distributions
- observation of phase equilibria and related kinetics.

Some major trends are given below.

2.5.1 Application of Radiotracers in Laboratory Determinations by Chemical Separation

Optimization and, eventually, actual performance of trace determinations in the analytical laboratory may be done efficiently by means of radiotracers. Inorganic applications usually rely on $\gamma$-emitting radionuclides, while organic (i.e. biological and medical) experiments are mostly based on $\beta$-emitters. A second distinction is that between off- and on-line measurements. Obviously, the latter are preferred whenever they are feasible.

An example of an inorganic application is met in the determination of $\text{Hg}^{II}$ in water by reduction with $\text{SnCl}_2$ and aeration; the escaping mercury vapor is trapped on active carbon. Figure 2(a–c) illustrate to this procedure.

Radionuclides used in the separation and determination of organic trace compounds by high-performance liquid chromatography and off- or on-line counting are listed in Table 2; Figure 3 shows the flow-sheet of the apparatus. The choice between off- and on-line counting depends on the scope of the experiment and the specific activity of the radiotracer. The advantages of off-line counting are the variable counting time, the stable and low count rate of the background and the absence of any influence of chemiluminescence. The accompanying disadvantages comprise the inevitable “breaking-up” of the originally continuous chromatogram, the risk of irreproducible fractions and the time-consuming laborious procedure. Off-line scintillation counting is convenient when a small number of well-separated peaks are expected and if the amount of radioactivity, governed by the specific activity, is low.

Flow-through detection with a water-miscible liquid scintillator implies its continuous addition, usually at flow rates between 0.1 and 1 mL min$^{-1}$ and subsequent mixing. The detector cell is $\sim 50 \mu$L in volume, thus appreciably larger than the usual $\sim 10 \mu$L cells of other detection methods. The advantages of flow-through counting are the automatic procedure and the high counting efficiency. The obvious disadvantage is band broadening in the cell.

Solvent segmentation based on postcolumn extraction/segmentation of the column eluate with a suitable liquid scintillation is the best option. (11)

$^a$ Specific activities given are about the maximum values specified for commercially available radiolabeled compounds or elements. TBq mmol$^{-1}$ unless stated otherwise.

$^b$ The maximum range given is calculated for pure $\beta$-emitters in water from the formula: Range in g cm$^{-2} = 0.11[(1 + 22.4 E_\beta^{2/3}) - 1]$ with $E_\beta$ in MeV.

Figure 3  Apparatus for flow-through liquid scintillation counting. 1 = injector, 2 = fraction collector.

3 MEASUREMENT OF SPATIAL DISTRIBUTIONS

3.1 Survey

In assessing spatial distribution, radiotracers are most often used to measure net mass transfer of a previously spiked component within a known matrix. Thus radioanalysis is just one of the options. Conversely, the measurement of isotopic exchange is open to isotopic methods only. Here radioanalysis has to compete with mass spectrometry in measuring coefficients of self-diffusion.

The oldest application in spatial distributions is the study of self-diffusion in metals. Relevant uses are met in the profiling of doping agents in semiconductors, tomography and the determination of diffusion coefficients in wetted granular solids and in liquids. In industrial pilot plants and factories, radiotracers are used to measure linear velocity and dispersion as mentioned in section 2.3.

3.2 Profiling in Solids

Flat solid surfaces of spiked samples are probed for their trace concentration profiles by abrasion or controlled
dissolution, followed by measurements on the material removed or the remaining aliquot. In general the first approach gives better precision but the actual advantage over measurement on the remaining aliquot depends strongly on the concentration profile.

The thickness of the layer removed in one step usually varies between 0.5 and 10 µm with a lower limit of ~0.1 µm. The radiotracer method thus fills the gap between macroscopic removal of surface layers and the physical methods for the submicron range.

A severe limitation is imposed by the required properties of the radiotracer and the mandatory combination of a radiochemical and solid-state laboratory which is found only in some university institutes and a few industrial laboratories. The use of special polishing apparatus with copper discs is also implied to obtain a precision of less than 1 µm. The amount removed is determined by microbalance weighing at a precision of ≤10 µg.

Counting of the remaining aliquot is restricted to β-emitting radionuclides and is performed with a solid anthracene detector. Collection of the abraded material on the copper discs and the surface of the remaining aliquot is feasible within 1%. In the case of silicon HF dissolution is necessary which precludes the use of a liquid scintillator for β-emitters and restricts detection to Cerenkov counting and individual quenching correction.

3.3 Radiography and Tomography

There is no possibility or need to discuss the whole field of present day radiotracer-based radiography. Its use in biology and medicine as thin layer radiochromatography is obvious. As a relatively new feature, the use of storage phosphor screens can be mentioned, as this has increased the sensitivity and widened the applicability of double labeling procedures.

From the beginning of the 1980s, computer-aided tomography of three-dimensional objects became a new branch of radionuclide application. As with radiography, this text does not endeavor to treat this new specialization in detail; only principles are signaled.

Tomography is either based on the variation of the object’s own γ-count rate with the position towards the detector or on the change in attenuation of transmitted photons or neutrons. The first approach may be based on previous neutron activation or an added tracer; the last option belongs to the medical imaging techniques which will not be considered here. Industrial and nuclear waste tomography use the same principle. The full width at half maximum of the scanning of a 198Au-source was ~7 mm in the early experiments. Much better spatial resolution is obtainable in examining used fuel elements through a <1 mm slit of ~1 m length, as performed at ECN, Petten.

Using a 241Am (59.5 keV) and a 137Cs (661 keV) source in conjunction with collimators of 1–5 mm and distances of 50–150 mm resulted in full width at half maximum of 5–40 mm. Comparable values (9–18 mm) were obtained in transmission and 131I-based emission experiments with phantoms. Off-line measurements on a neutron-activated bone sample by way of 24Na, $T_{1/2} = 15$ h, gave a spatial resolution of 1–2 mm.

On-line measurements in the $1.8 \times 10^{12}$ cm$^{-2}$ s$^{-1}$ neutron beam at the Grenoble HFR gave ~7 mm full width at half maximum for CdCl$_2$ test pellets of that size.

Apart from the routine measurements on used fuel elements, as performed at ECN, no systematic application of radionuclide-based tomography is reported: simulated fuel and a test loop experiments with 24Na are scarce examples. In sharp contrast, the use of radioactive sources in industrial trouble-shooting as “go devils” is an established practice.

3.4 Diffusion in Wetted Granular Solids

Probably the most practical consequence of differences in element speciation is the variation in environmental mobility. Obviously the water content and the apparent diffusion coefficient of an inert tracer, i.e. one which does not interact with the solid, have to be determined. These data will then serve as reference values.

The use of a miniaturized system for diffusion measurements was first demonstrated in the case of traces of 239Pu. Then it was applied to self-diffusion under equilibrium conditions.

Two identical cylinders are pressed together in a syringe. One part contains the radionuclide; the diffusion into the other section is measured. If a “weightless” spike is used, operation is under equilibrium conditions. This procedure yields the coefficient of self-diffusion, which for trace constituents is equal to the effective diffusion coefficient. When a component is involved which is present in solution only the apparent diffusion coefficient(s) obtained reflect(s) the tortuosity and constructivity of the void fraction(s). Experimentally, these two effects combine into one “restriction factor”.

If a component is present in both the solid and the liquid phase and if the added radiotracer exchanges rapidly over the phase border, its diffusion will reflect the distribution ratio. When the element involved is present in more than one chemical form the result of the diffusion experiment will depend on the rate of isotopic exchange between the added spike and the (other) species. Only in the limiting cases of either very rapid exchange or no exchange at all, radiotracer diffusion will yield valuable information. Rapid exchange leads to the determination of the mass-averaged apparent diffusion coefficient. No exchange at...
all implies the determination of the apparent diffusion coefficient of the spiked chemical form. The simple diffusion Equation (8) applies to a radiotracer which is exclusively present in solution and in one chemical form only and for the case of semi-infinite media.

\[
\frac{\partial (ac)}{\partial t} = D \frac{\partial^2 (ac)}{\partial x^2}, \quad (8)
\]

where \( a \) is the specific activity (Bq g\(^{-1}\)), \( c \) is the concentration (g L\(^{-1}\)), \( D \) is the coefficient of self-diffusion (m\(^2\) s\(^{-1}\)), \( x \) is the position (m) and \( t \) is time (s).

At chemical equilibrium, for a “weightless” spike, this expression reduces to Equation (9)

\[
\frac{\partial a}{\partial t} = D \frac{\partial^2 a}{\partial x^2}, \quad (9)
\]

From a plot of \( \ln a \) against \( x^2 \) and curve fitting to the solution of Equation (9) for a finite system\(^{(23)}\) the apparent diffusion coefficient together with information about the eventual coexistence of more than one flow-channel and their relative importance are obtained.

Under equilibrium conditions and with rapid isotopic exchange Equation (10) gives the experimentally apparent \( D \)-value

\[
D_e = \frac{D}{1 + (m_S/m_L)} \quad (10)
\]

where \( D \) refers to the “true” or unretarded diffusion coefficient in an aqueous solution, \( r \) to the mentioned restriction factor and \( m_S/m_L \) to the ratio of the exchangeable-masses of the element involved in the solid and liquid phases. Whether the assumption of fast isotopic exchange is valid or not can be verified by varying the time lag between the application of the radiotracer to one compartment and the actual joining of the two sections. If this has no influence on the result, the condition is fulfilled.

As an inert radiotracer, tritiated water is used. Environmental investigations refer most often to anions as these feature the highest mobilities. Suitable radiotracers are \(^{74}\)AsO\(_3^+\), \(^{75}\)SeO\(_2^+\), and \(^{75}\)SeO\(_3^+\), \(^{99}\)MoO\(_2^+\) and \(^{124}\)SbO\(_3^+\). It can be concluded that a specific activity of \( \leq 10 \mu\text{Ci g}^{-1}\) is sufficient for adding a “weightless” spike of \( \leq 20 \mu\text{g g}^{-1}\).

Figure 4 summarizes the procedure. About 3 g of the sample material is mixed with 0.9 mL of tracer solution and carefully homogenized. The diffusion tube consists of polythene with internal diameter 8 mm and length 70 mm. The interface of the two segments is gently marked with a tiny drop of \(^{170}\)Tm solution.

After a storage time of 5–15 days, the combined segments are taken out, frozen in liquid nitrogen and sliced into 0.5–1 mm coupons. These are dried, weighted and counted. Data are processed to find the most likely \( D \)-value. Figure 5 gives the result for the diffusion of tritiated water through a fly-ash. The estimated value of the apparent diffusion coefficient is expressed as \( pD_e \). The usual error is 0.1 unit.
3.5 Diffusion in Liquids

The precise and accurate determination of diffusion coefficients of trace constituents (either of ionic or of molecular nature) in dilute, mostly aqueous, solutions is one of the obvious uses of radiotracers in the field of spatial speciation.

The main advantage of radiotracer experiments here, as in wet granular solids, is the possibility of measuring at zero diffusion gradient.\(^{(24)}\) Two techniques have been put forward, based respectively on a glass frit diaphragm\(^{(25)}\) and an open capillary within a large tank.\(^{(24)}\)

Initially, a diaphragm cell of \(\sim 100 \text{mL}\) was used.\(^{(28)}\) Later, the capillary procedure came into use, offering the advantage of a small spiked volume of \(\geq 10 \mu\text{L}\) per capillary. It implies stirring the outside solution and thus requires rigorous precautions against turbulent flow and mechanical dragging of the spiked liquid from the capillaries. In the final version just one capillary is used, mounted within the well of a bored-through plastic scintillator which monitors continuously the remaining radioactivity. The whole apparatus is mounted in a thermostated room. With a (small) correction for the variation of the counting geometry with proceeding diffusion, a precision of \(\sim 0.2\%\) can be reached.\(^{(26,27)}\)

Reports on the use of the capillary procedure are found in Kepak et al.\(^{(29)}\) and Podhajecky et al.,\(^{(30)}\) while a reexamination of the diaphragm procedure is given by Podhajecky et al.\(^{(31)}\)

4 OBSERVATIONS ON PHASE EQUILIBRIA AND RELATED KINETICS

4.1 Survey

Within a system in (apparent) equilibrium, elements often occur in different physical phases. The potential use of radiotracers in measuring these distributions, and the kinetics with which they are reached, is obvious. The early, often “classical”, applications are mentioned in most textbooks on radiochemistry. The number of literature reports on the subsequent use in all branches of science, technology and medicine is enormous. Virtually all applications refer to the measurement of net mass transport (cf. section 2.2).

Current literature abounds with (more or less) defined procedures for physical speciation,\(^{(32–41)}\) particulate matter and colloids in natural waters\(^{(42–54)}\) and availability measurements on trace metals in granular solid wastes.\(^{(55–57)}\) Eventually these investigations pertain to the occurrence and distribution of radionuclides from nuclear bomb tests and waste reprocessing.\(^{(58–67)}\) Quoted references give some examples only.

A methodical application is comparison of analytical techniques on water containing particulate matter.\(^{(68)}\) Equally, preconcentration and storage have been examined with the help of radiotracers. The contact time between water sample and container, whether polythene or glass, should not exceed more than a few minutes. In situ immobilization, eventually combined with preconcentration, is imperative. Scavenging with active carbon after adsorption of a suitable chelating agent is a possibility.\(^{(42)}\) Collection on Chelex-100 or on a combination of an anion and cation exchanger is well known; a survey is given by Florence.\(^{(69)}\)

Freezing, in combination with freeze-drying, is the best way of preserving the sample in its original state.\(^{(70)}\) Acidification to \(pH \sim 1–2\) is justified only after thorough elimination of particulate matter, to avoid desorption.\(^{(71)}\) Using \(^{203}\text{Hg}\), it was found that \(\text{Hg}^{II}\) desorbs completely at \(pH = 0.1\) with a half-life of \(\sim 30\) min.\(^{(72)}\)

The quest for well-defined and generally applicable speciation schemes has been successful in a few cases only. The separation of colloids from fresh water samples by the hollow fiber technique\(^{(47,52)}\) is an example; the standard leaching test on coal fly-ash is another,\(^{(55)}\) although a recent comparison revealed some systematic discrepancies between the various modes.\(^{(71)}\) Sequential leaching of soils by a series of increasingly aggressive solutions has been applied in a multitude of schemes, all of limited significance. Several articles\(^{(72–82)}\) giving examples have been published.

Applications of radiotracers to adsorption and desorption measurements and in isotopic exchange experiments were mentioned in section 2. Three practical applications are considered here:

- measurement of speciation controlled diffusion through soils\(^{(82,84)}\)
- kinetic association experiments with colloids in water\(^{(85)}\)
- evaporation kinetics of traces or organic pollutants from surface water.\(^{(86)}\)

4.2 Speciation-controlled Diffusion

Figure 6 outlines the apparatus used. The “steady state” experiment imposes a linear gradient over the test sample but it takes a considerable time to reach it.\(^{(83)}\) Typical experiments with sand samples take \(\sim 10^3\) h. The radionuclide concentration in the unspiked reservoir is always much lower than that in the spiked compartment. This eliminates back diffusion.

The concentration in the unspiked cell is monitored until its rate of increase becomes constant. Relevant mathematics are given by Crank.\(^{(83)}\) The crucial feature is that \(\partial^2c/\partial x^2\) is zero and thus \(\partial c/\partial x\) is constant.
from a separate equilibration tank.

section 4.1, except for its much larger dimensions. These with $^{125}$I($T^{1/2} = 60$ day), as a function of the solid/solute ratio. Data were found to follow Freundlich isotherms.

“Infinite couple” or “back-to-back” geometry has two cylinders of material, one of them spiked, pressed together. It thus resembles the array discussed in section 4.1, except for its much larger dimensions. These enable the use of large aliquots of groundwater, taken from a separate equilibration tank.\(^{(86)}\)

The effective diffusion coefficient and distribution constant was determined for both $^{1}$ and $^{64}$I, spiked with $^{125}$I($T^{1/2} = 60$ day), as a function of the solid/solute ratio. Data were found to follow Freundlich isotherms.

4.3 Kinetics of Colloid Association

The use of spikes in radiotracers to determine recoveries in physical and chemical separations is obvious. Their most apparent application is met in the experiments on hollow fiber preconcentration, using an “Amicon” apparatus, of naturally occurring radionuclides.\(^{(47,48,66,85-88)}\) Cartridges with nominal molecular weight cut-off of $10^5$, $10^4$ and $10^3$ are applied. Isolated fractions are analyzed by $\gamma$-spectrometry.

Kinetic association experiments are performed with the apparatus shown schematically in Figure 7. The sample is introduced into the test chamber and transported by a peristaltic pump to a mixing chamber and separator. The ultrafiltrate returns to the test chamber while the retained colloids go to the mixing chamber. The decrease in tracer radioactivity in the test solution reflects dilution, association with naturally occurring colloids and, eventually, sorption to the equipment.

It is found that equilibrium is usually reached in 1–2 h. The majority of naturally occurring $^{60}$Co and added $^{65}$Zn is in the $>10^4$ D fraction.

An alternative to dialysis may be found in electrophoresis.\(^{(33,64)}\) Free liquid electrophoresis was applied to speciation studies of radium in natural waters using $^{224}$Ra as the radiotracer.\(^{(64)}\) Results indicate that in $10^{-2}$ M chloride solutions the $^{41}$Ra$^{2+}$ cation is the main chemical species between pH = 2 and pH = 7.

4.4 Evaporation Kinetics of Traces of Organic Pollutants

Radiotracers are applied to environmentally important kinetics. In evaporation measurements, the overall mass transfer coefficient, $K$, in mol min$^{-1}$ cm$^{-2}$ has to be obtained.\(^{(89)}\) To this end, evaporation experiments are conducted with labeled trace constituents from open vessels with a known gas–liquid surface area. The concentration of the (volatile) trace compound decreases exponentially with a characteristic constant $KS/V_L$ for a given surface area $S$ (cm$^2$) and liquid volume $V_L$ (mL).

In a closed flask, the equilibrium concentration in the solution reflects the thermodynamic potential of the
trace constituent in the liquid phase. By measuring this equilibrium as a function of the initial concentration, eventual deviation from ideality can be detected.

“Carrier-free” $^3$H- or $^{14}$C-labeled compounds are used to spike stock solutions of the chemicals of interest. With commercially available specific activities of $\sim 1$ TBq $^3$H (m mol$^{-1}$), a liquid volume of $\sim 50$ mL, an aliquot size of 2 mL and a counting time of 100 min, the limit of determination at $\sigma_{rel} \sim 1\%$ is $10^{-2}$ ppb. For $^{14}$C-labeled compounds of $\sim 2$ GBq $^4$C (m mol$^{-1}$) the lower limit is $\sim 5$ ppb.

Rutherford backscattering spectroscopy (RBS) is one of the most powerful techniques for measuring elemental depth profiles. It allows quantitative and nondestructive analysis with a reasonable depth resolution. In conventional RBS (combination of 1–4 MeV He ions with a silicon surface-barrier detector), the typical depth resolution is about 10 nm and the typical mass resolution is about 1 u for light elements (mass number \(M < 20\)) and about 20 u for heavy elements (\(M \approx 200\)). Sensitivity of 100 ppm can be easily obtained for heavy elements in light hosts although analysis of light elements in heavy hosts is difficult. In the present article, physical concepts which RBS relies on are briefly introduced. Some examples of analyses are demonstrated and several advanced techniques which have been developed to improve capabilities of the conventional RBS are discussed.

1 INTRODUCTION

The analysis of the surface and near-surface region of solids has become an important field of science and technology. RBS is one of the most powerful methods among a number of analyzing techniques. In RBS, high-energy ion beams, usually H or He ions with energies in the range 1–4 MeV, are used as probes. A sample is irradiated by the ion beam. Almost all ions penetrate deep inside the sample up to ca. 10 µm until they entirely lose their kinetic energy. During the penetration some ions collide with the target atoms and are subject to elastic Coulomb scattering (Rutherford scattering) between the projectile and the target nuclei and may be backscattered from the sample. The energy of the ion backscattered from the target atom depends on the target atom mass. This allows compositional analysis of a surface region of several micrometers by measuring the energy spectrum of the backscattered ions. Figure 1 illustrates a schematic set-up of RBS and an example of an energy spectrum for a two-element thin film on a low-mass substrate. The ions scattered from each element form a separated peak. The number of target atoms in the film can be derived from the peak yields and the peak width gives the film thickness. Table 1 summarizes the features of standard RBS and can be used as a rough guide.

The method was first employed by nuclear physicists to analyze their targets in 1951. Extensive application to material science began in the late 1960s. The technique has been refined and now constitutes one of the most common methods for compositional analysis of the surface region. RBS has many outstanding features:

1. RBS is a nondestructive method of analysis.
2. It allows quantitative analysis of all elements simultaneously except for hydrogen.
3. RBS has a depth resolution typically of about 10 nm, which can be improved up to monolayer resolution in the surface region with special equipment.
4. The measurement time is typically as short as several minutes.
5. Sensitivity of RBS is about 100 ppm for heavy elements although it is not so good for light elements.

RBS relies on the following physical concepts:

1. The kinematic factor of the elastic scattering which describes the reduction of incident energy in a collision between the probe ion and the target atom.

SSB, silicon surface barrier.

The resulting energy of the scattered ion increases with target atom mass. This allows identification of the target atom by measuring the scattered ion energy.

2. The differential scattering cross-section which gives the probability of scattering. This allows basic quantitative analysis without a standard sample.

3. The stopping power which is defined by the energy loss of the ion per unit path length inside the target. The energy of the backscattered ion depends on the depth from which the ion was scattered because the path length is proportional to the depth. This allows the depth profiling of elements in the target.

4. The energy-loss straggling which is the fluctuation of the energy loss arising from the statistical feature of the energy-loss process. This determines the intrinsic depth resolution.

There are numerous reviews on RBS\(^{(2–4)}\) and for the state of the art reader can refer to relevant conference proceedings such as ion beam analysis (IBA), Conference on the Application of Accelerators in Research and Industry (CAARI), European Conference on Accelerator Applications in Research and Technology (ECAART) and Nuclear Microprobe Technology and Applications (NMTA). Most have been published in *Nuclear Instruments and Methods* in the Physics Research section B.\(^{(5)}\)

2 FUNDAMENTALS

2.1 Kinematics of Ion–Atom Collisions

When an ion is scattered from a target atom at an angle $\theta$, the ratio of the scattered-ion energy $E$ to the incident energy $E_0$ can be calculated using the laws of conservation of energy and momentum, Equation (1)

$$K = \frac{E}{E_0} = \frac{(M_2^2 - M_1^2 \sin^2 \theta)^{1/2} + M_1 \cos \theta}{M_1 + M_2}$$

(1)
where $M_1$ and $M_2$ are masses of the incident ion and the target atom, respectively. The binding energy of the target atom and its thermal vibration are neglected in the derivation of Equation (1). These effects are negligibly small in collisions between ions with mega-electron volt energy and target atoms. It is clear that the energy ratio $K$, called the kinematic factor, is determined by the mass ratio $M_2/M_1$ and the scattering angle $\theta$. The basic idea of RBS relies on this equation. Figure 2 shows the kinematic factor as a function of the mass ratio $M_2/M_1$. The kinematic factor, and thus the energy of the scattered ion, increases monotonically with the mass ratio indicating that the target atom mass can be determined from the observed energy of the scattered ion.

The mass resolution is defined by Equation (2)

$$\delta M_2 = \frac{\delta E}{E_0} \sqrt{\frac{dK}{dM_2}}^{-1}$$

where $\delta E$ is the overall energy resolution of the RBS system. The dominant contribution to $\delta E$ comes from the energy resolution of a SSB detector which is commonly used in RBS. Figure 3 displays the calculated mass resolution for 2-MeV H, He, and C ions, where the typical energy resolutions of the SSB detector (i.e. $\delta E = 10$, 15, and 50 keV for H, He, and C ions, respectively) are used for $\delta E$. The results at different scattering angles are also shown for 2-MeV He ions. A mass difference of 1 u can be resolved for light elements ($M_2 < 40$ u) with 2-MeV He ions. The resolution, however, becomes worse very rapidly with increasing $M_2$ and reaches $\delta M_2$ ca. 20 u at $M_2$ ca. 200 u.

For better mass resolution, heavy ions are usually employed. Although the energy resolution of the SSB detector is worse for heavy ions, the resulting mass resolution for C ions is better than for He ions and $\delta M_2 = 1$ u is achieved up to $M_2$ ca. 50 u with 2-MeV C ions. The resolution can be improved considerably using the time-of-flight (TOF) technique for energy analysis instead of the SSB detector in heavy ion RBS (HIRBS). The details of the heavy ion RBS will be discussed in section 4.1.

### 2.2 Rutherford Cross-section

The scattering cross-section $\sigma$ is an effective area associated with the colliding particles. When projectile ions impinge on a thin target film of thickness $t$, the scattering yield is given by Equation (3)

$$Y_{\text{tot}} = \frac{N_0 \sigma Q}{\cos \alpha}$$

where $N$ is the volume density of the target atom, $Q$ is the number of incident ions, and $\alpha$ is the incident angle (the definition of $\alpha$ is shown in Figure 1). In RBS, the ions scattered at a particular scattering angle $\theta$ are measured by a detector with a finite acceptance solid angle $\Delta \Omega$. The number of these ions can be calculated (Equation 4) with an angular differential cross-section $d\sigma/d\Omega$

$$Y(\theta) = N_0 \frac{d\sigma}{d\Omega} \Delta \Omega Q \cos \alpha$$

The differential cross-section for Coulomb scattering (Rutherford cross-section) is given by an analytical formula (Rutherford formula), Equation (5)

$$\left( \frac{d\sigma}{d\Omega} \right)_R = \left( \frac{Z_1 Z_2 e^2}{4E} \right)^2 \times \frac{4 \sqrt{(M_2^2 - M_1^2 \sin^2 \theta) + M_2 \cos \theta}}{M_2 \sin^2 \theta \sqrt{M_2^2 - M_1^2 \sin^2 \theta}}$$

![Figure 2: Kinematic factor $K$ as a function of the ratio of the target mass to the ion mass $M_2/M_1$.](image)

![Figure 3: Mass resolution for 2-MeV H, He and C ion beams as a function of target mass $M_2$. Typical energy resolution of the SSB detector is used in the calculation.](image)
where \( Z_1, Z_2 \) are atomic numbers of incident ion and target atom, respectively and \( E \) is the incident energy. This simple formula guarantees to extract quantitative data about abundances of elements from RBS spectra. The cross-section is proportional to \( Z_2^2 \), indicating high sensitivity for heavy elements in RBS. A useful number in evaluating the Rutherford cross-section is \( e^2 = 14.4 \text{ eV} \cdot \text{Å} \) (1 Å = \( 10^{-10} \text{ m} \)). For example, 1 MeV He\(^+\) ions of total dose 1 μC are incident on a Si film of \( t = 1000 \text{ Å} \) at \( \alpha = 0^\circ \). The differential cross-section is calculated to be \( (d\sigma/d\Omega)_R = 1.126 \times 10^{-8} \text{ Å}^2/\text{sr} \) at \( \theta = 150^\circ \). Using a typical acceptance angle of SSB detectors, \( \Delta \Omega = 5 \text{ msr} \) the yield is given by Equation (6)

\[
Y = 4.994 \times 10^{-2} \text{ Å}^{-3} \times 1000 \text{ Å} \times 1.126 \times 10^{-8} \text{ Å}^2/\text{sr}^{-1} \\
\times 5 \times 10^{-3}\text{sr} \times \frac{1 \times 10^{-6}}{1.602 \times 10^{-19}} \approx 17500 \quad (6)
\]

The associated statistical error is \( 1/\sqrt{17500} = 0.8\% \). This means the thickness of the film can be determined with an accuracy less than 1% in this case.

### 2.3 Non-Rutherford Cross-sections

The Rutherford cross-section can be used in situations where the incident ion energy is in the order of 1 MeV \( \text{u}^{-1} \). The cross-section deviates from the Rutherford formula in both high-energy and low-energy regions. On the low-energy side, the screening effect due to the bound electrons in the target atom reduces the cross-section from the Rutherford formula. The cross-section cannot be given by a simple analytical formula like Equation (5). The screened Coulomb potential is given by Equation (7)

\[
V(r) = \frac{Z_1 Z_2 e^2}{r} \phi \frac{r}{a} \quad (7)
\]

where \( \phi \) is the screening function and \( a \) is the screening length. There are several analytical formulas for the screening function given by a sum of exponential terms, Equation (8)

\[
\Phi(z) = \sum_{i}^{n} \alpha_i e^{-\beta_i z} \quad (8)
\]

where \( \{ \alpha_i \} = \{ 0.1, 0.55, 0.35 \} \), \( \{ \beta_i \} = \{ 6.0, 1.2, 0.3 \} \) for Möllère’s screening function \(^{(6)}\) \( (a = 0.8853 a_{th}(Z_1^{1/2} + Z_2^{1/2} - 2)/3) \) is commonly used) and \( \{ \alpha_i \} = \{ 0.18175, 0.50986, 0.28022, 0.028171 \} \), \( \{ \beta_i \} = \{ 3.1998, 0.94229, 0.40290, 0.20162 \} \) for Zieler–Biersack–Littenmark’s screening function \( (a = 0.8853 a_{th}(Z_1^{2/3} + Z_2^{2/3})^{-1}) \) is used. \(^{(7)}\)

Using the screening function, the differential cross-section can be calculated numerically. Algorithms for rapid computations are proposed by Mendenhall and Weller. \(^{(8)}\) A useful analytical formula for the screening correction valid for large scattering angles is given by L’Ecuyer et al., \(^{(9)}\) Equation (9)

\[
\frac{d\sigma/d\Omega}{(d\sigma/d\Omega)_R} = 1 - 0.049 Z_1 Z_2^{4/3} E_C \quad (9)
\]

where \( E_C \) is the center-of-mass kinetic energy in kiloelectron volts. Examples of the results calculated with Equation (9) together with the result of exact numerical calculation are shown in Figure 4. The deviation from the Rutherford cross-section is large for heavy elements and the correction formula for Equation (9) is reasonably good for both heavy and light elements. Although the deviation for 1-MeV He–Au scattering is about 4% and the Rutherford formula may not be used in a precise measurement, Equation (9) can be safely used even in this situation. It must, however, be noted that Equation (9) does not contain the scattering angle \( \theta \) and is valid only for large \( \theta \). At smaller scattering angles, the screening effect becomes large.

On the high-energy side, the incident ion may approach to the target nuclei within the range of the nuclear force. This causes deviation from the Rutherford cross-section. The deviation is large for light elements because the Coulomb barrier of the nucleus is low for light elements. An empirical formula to estimate the threshold energy, above which the deviation from the Rutherford cross-section for 160° < \( \theta < 180° \) is larger than 4%, is given by Leavitt and McIntyre, \(^{(10)}\) Equations (10–12)

\[
E_{th} = (0.12 \pm 0.01)Z_2 -(0.5 \pm 0.1) \text{ MeV for } \text{H} \quad (10)
\]
\[
E_{th} = (0.25 \pm 0.01)Z_2 + (0.4 \pm 0.2) \text{ MeV for } \text{He} \quad (11)
\]
\[
E_{th} = (0.330 \pm 0.005)Z_2 + (1.4 \pm 0.1) \text{ MeV for } \text{Li} \quad (12)
\]

![Figure 4](image-url)  
**Figure 4** Screening correction for the scattering cross-section as a function of the incident ion energy. The results of the numerical calculation (solid lines) as well as those of the analytical formula (dashed lines) are shown for He–Si and He–Au scattering.
In contrast to the correction for screening effect, no practical methods exist for rapid accurate estimation of the nuclear force correction. The cross-section depends on both the ion energy and the scattering angle in a complicated manner (e.g. Figure 14). Nevertheless, high-energy ions are useful in some cases, especially in analysis of light elements. The standard RBS is less sensitive for light elements due to the small Rutherford cross-sections of light elements (the cross-section is proportional to the square of the target atomic number). The non-Rutherford cross-sections for light elements are frequently enhanced by one or two orders of magnitude while those for heavy elements may remain as a Rutherford cross-section. This improves the sensitivity for light elements. The details will be discussed in section 4.4.

2.4 Stopping Power

An energetic ion passing through a solid loses its energy primarily through excitation of electrons. The rate of the energy loss per unit path length, \( \frac{dE}{dx} \), is called stopping power and understanding the stopping power has been a subject of extensive studies. Using the first-order perturbation theory, the stopping power is given by\(^{11} \) Equation (13)

\[
\frac{dE}{dx} = \frac{4\pi Z_1^2 Z_2 N e^4}{mV^2} \ln \left( \frac{mV^2}{I} \right)
\]

where \( m \) is the electron mass, \( V \) the velocity of the ion, and \( I \) \((\approx 10 \times Z_2 \text{ eV})\) is the mean excitation energy of the target electrons. This equation, called the Bethe–Bloch formula, is used as a guide in semi-empirical fitting of stopping power data to provide semi-empirical formulas. A number of tables are available to calculate stopping powers reasonably accurately.\(^{12–14} \) Figure 5 shows examples of the stopping powers of Si and Au for H and He ions calculated with the tabulated values given by Andersen and Ziegler.\(^{12,13} \) The stopping power has a broad maximum around 1 MeV for He ions and around 100 keV for H ions. The maximum energy and the maximum stopping power increases with both projectile and target atomic number. The stopping power for megaelectron-volt He ions is several times larger than that for megaelectron-volt H ions. This indicates that better depth resolution is available for He ions.

In order to estimate the stopping power of a compound, it is convenient to introduce stopping cross-section defined by Equation (14)

\[
\varepsilon = \frac{1}{N} \left( \frac{dE}{dx} \right)
\]

The stopping power of a compound \( A_mB_n \) can be calculated using Bragg’s rule, which is based on the simple assumption that the constituent elements act independently in the energy loss process, Equation (15)

\[
\left( \frac{dE}{dx} \right)_{A_mB_n} = N_{mol}[n\varepsilon(A) + m\varepsilon(B)]
\]

where \( \varepsilon(A) \) and \( \varepsilon(B) \) are the stopping cross-sections of the constituents and \( N_{mol} \) is the molecular density. This neglects the effect of chemical bonding but gives reasonably accurate values for megaelectron-volt light ions.

The relationship between the energy of the scattered ion and the depth at which the ion is scattered can be calculated using the stopping power, the kinematic factor, and the geometry of the scattering. Neglecting the variation of the stopping power along the ion path, the energy of the ion scattered from a target atom at a depth \( t \) is given by Equation (16)

\[
E(t) = K E_0 - \left( \frac{dE}{dx} \right)_{\text{in}} \frac{t}{\cos \alpha} - \left( \frac{dE}{dx} \right)_{\text{out}} \frac{t}{\cos \beta}
\]

where the subscripts in and out refer to the inward path and outward path, respectively, and \( \alpha \) and \( \beta \) are the incident and exit angles, respectively. For a thin surface layer, the variation of the stopping power is small and the use of an average value is a good approximation. The variation in energy \( \delta E \) corresponds to a variation in depth \( \delta t \) through Equation (17)

\[
\delta E = -[S] \delta t
\]

where \([S]\) is commonly called the energy-loss factor and is given by Equation (18)

\[
[S] = K \left( \frac{dE}{dx} \right)_{\text{in}} \frac{1}{\cos \alpha} + \left( \frac{dE}{dx} \right)_{\text{out}} \frac{1}{\cos \beta}
\]
The depth resolution depends on the overall energy resolution, the stopping power, and the geometry. The energy resolution is normally composed of three contributions: the energy spread of the incident beam \( \delta E_{\text{in}} \), the detector resolution \( \delta E_{\text{det}} \), and the energy loss straggling \( \delta E_{\text{s}} \) (the last of these, \( \delta E_{\text{s}} \), will be discussed in detail in the next section). Assuming these contributions are independent, the overall resolution is given by Equation (19)

\[
(\delta E)^2 = (\delta E_{\text{in}})^2 + (\delta E_{\text{det}})^2 + (\delta E_{\text{s}})^2
\]  

(19)

For example, in the case of 2-MeV He on Au at \( \theta = 0^\circ \) and \( \beta = 30^\circ \) (\( \theta = 150^\circ \)), the energy-loss factor is calculated to be 135 eV Å\(^{-1}\). Using a typical energy resolution in the standard RBS, \( \delta E = 15 \text{ keV} \) and a depth resolution of 11 nm is obtained. The depth resolution can be improved up to ca. 2 nm simply by using a grazing-angle technique, usually with a grazing exit angle, for example \( \beta \text{ ca. } 85^\circ \). In the grazing-angle geometry, the acceptance angle of the SSB detector should be much smaller than the grazing angle. Otherwise the distribution of \( \beta \) and with it the distribution of \([S]\) makes the depth resolution worse.

2.5 Energy-loss Straggling

The energy-loss process described in the previous section has a stochastic feature. The slowing down of the ion has a stochastic feature. The slowing down of the ion is a random process. The energy-loss factor is calculated to be 135 eV Å\(^{-1}\). Using a typical energy resolution in the standard RBS, \( \delta E = 15 \text{ keV} \) and a depth resolution of 11 nm is obtained. The depth resolution can be improved up to ca. 2 nm simply by using a grazing-angle technique, usually with a grazing exit angle, for example \( \beta \text{ ca. } 85^\circ \). In the grazing-angle geometry, the acceptance angle of the SSB detector should be much smaller than the grazing angle. Otherwise the distribution of \( \beta \) and with it the distribution of \([S]\) makes the depth resolution worse.

\[
\Omega_{\text{rb}}^2 = 4\pi Z_2^2 Z_2 e^4 N_t
\]

(20)

and has been extended to lower energies by many authors. A useful analytical formula was given by Lindhard and Scharff,\(^{(15)}\) Equation (21)

\[
\frac{\Omega^2}{\Omega_{\text{B}}} = L(\chi) = \begin{cases} 
0.68\chi^{1/2} - 0.08\chi^{3/2} & \chi \leq 3 \\
1 & \chi \geq 3
\end{cases}
\]

(21)

where \( \chi = (V/v_B)^2/Z_2 \), \( V \) is the ion velocity, and \( v_B \) \((= 2.2 \times 10^8 \text{ cm s}^{-1})\) the Bohr velocity. More refined models were developed by Bonderup and Hvelplund,\(^{(17)}\) Chu,\(^{(18)}\) and Besenbacher et al.\(^{(19)}\)

For compounds, an additive rule similar to Bragg’s rule was proposed,\(^{(18)}\) Equation (22)

\[
\frac{\Omega^2(A_m B_n)}{N_{\text{mol}} t} = \frac{m\Omega^2(A)}{N_A t} + \frac{n\Omega^2(B)}{N_B t}
\]

(22)

The contribution of the energy-loss straggling to the energy resolution is given by Equation (23)

\[
(\delta E_s)^2 = 8 \ln 2 \left( K^2 \Omega_{\text{in}}^2 + \Omega_{\text{out}}^2 \right)
\]

(23)

where \( 8 \ln 2 \) is a conversion factor from the standard deviation to the full width at half maximum, and \( \Omega_{\text{in}} \) and \( \Omega_{\text{out}} \) are the straggling in inward and outward paths. For mega-electron-volt H and He ions incident on layers \( \leq 100 \text{ nm} \), the straggling is small (e.g. \( \Omega_{\text{in}} \text{ ca. } 2.7 \text{ keV} \) for He–Si at \( t \text{ ca. } 100 \text{ nm} \)) compared to the resolution of the SSB detector (\( \delta E_{\text{det}} \text{ ca. } 15 \text{ keV} \) for mega-electron-volt He) and can be neglected in the obtainable depth resolution in the standard RBS. The contribution of the energy-loss straggling, however, increases with \( t^{1/2} \) and the straggling sets a fundamental limit to the depth resolution at deeper layers.

3 STANDARD RUTHERFORD BACKSCATTERING SPECTROSCOPY

3.1 Apparatus

In the standard RBS, 1–4-MeV He ion beams and a SSB detector are commonly used. Although both the mass and depth resolutions are poorer for H ions than for He ions, H ions are sometimes used in RBS in order to analyze deeper regions. Ions generated by an ion source are accelerated by an electric field. The most widely used devices for the production of a mega-electron-volt ion beam are the Van de Graaff-type and Cockcroft-and Walton-type accelerators. The accelerated ions are analyzed by a magnet to eliminate contaminant ion species and to select the ion energy. The calibration of the analyzing magnet is usually done using resonant nuclear reactions. After passing the analyzing magnet, the ion beam is collimated by apertures to a size of ca. 1 mm and introduced to a scattering chamber where targets are mounted on a manipulator. The beam current is usually monitored by target current or a beam monitor system installed between the final aperture and the target. The typical beam current is of the order of 10 nA. For a channeling measurement, the beam divergence angle and the precision of the manipulator should be less than 1 mrad.

A SSB detector is installed inside the chamber to measure the energy spectrum of scattered ions. The SSB detector is basically a Schottky barrier diode. A reverse bias is applied to make a depletion region of the order of 100 μm which is greater than the range of the mega-electron–volt light ions. The electron–hole pairs created by the ion in the depletion region are swept by the high electric field and collected. The quantity of charge collected bears a linear relationship to the total energy spent to create electron–hole pairs (about 3.6–3.7 eV per electron–hole pair). The linearity between the collected charge and the ion energy is quite good for mega-electron-volt light ions. The signal from the detector is amplified.
by a preamplifier and a linear amplifier and sent to a pulse-height analyzer (PHA). The PHA stores pulses of a given height in a given channel. The relation between the channel number and the ion energy can be calibrated by measuring ions of known energy, for example α particles from $^{241}$Am. It should be noted that the energy lost in the entrance window as well as the energy lost to nuclear scattering do not contribute to the pulse height. The equivalent thickness of the window is about 100 nm, which corresponds to about 30 keV loss for 1-MeV He. These effects are serious for heavy ions and must be taken into account in the conversion procedure from pulse height to ion energy, especially in the low-energy region.

### 3.2 Thin Film Analysis

An example of RBS spectrum for a high-$T_c$ superconductor thin film deposited on a Si substrate is depicted in Figure 6.\(^{20}\) The film was prepared by ion beam sputtering of $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_7$. The peaks for Bi, Sr, Cu, and Ca are well separated and the oxygen peak can be clearly seen on top of the Si signal. The integrated counts $Y_i$ for each element can be accurately determined. The areal density of element $i$ is obtained from Equation (4) as

$$n_i = N_{i,t} = \frac{Y_i \cos \alpha}{(\sigma/d\Omega)_i \Delta \Omega}$$  \hspace{2cm} (24)

Although precise measurements of the ion energy $E$, the scattering angle $\theta$, the detector acceptance angle $\Delta \Omega$, and the incident ion number $Q$ are necessary to estimate the absolute areal density $n_i$, an average stoichiometric ratio can be obtained without these values, Equation (25)

$$\frac{N_i}{N_i^\text{ref}} = \frac{Y_i}{Y_i^\text{ref}} \left( \frac{\sigma}{d\Omega}_i \right) = \frac{Y_i}{Y_i^\text{ref}} \left( \frac{Z_i}{Z_i^\text{ref}} \right)^2$$  \hspace{2cm} (25)

The composition of the film shown in Figure 6 can be determined to be $\text{Bi}_1\text{Sr}_1\text{Ca}_{0.9}\text{Cu}_{1.4}\text{O}_7$ using this equation.

In order to estimate the absolute areal density $n_i$ using Equation (24), a standard sample implanted with a heavy element of a known areal density $N_{i,\text{ref}}$ is sometimes used, Equation (26)

$$n_i = N_{i,t} = \frac{Y_i}{Y_{i,\text{ref}}(\sigma/d\Omega)_i} N_{i,\text{ref}} \approx \frac{Y_i}{Y_{i,\text{ref}}} \left( \frac{Z_i}{Z_i^\text{ref}} \right)^2$$  \hspace{2cm} (26)

where $Y_{i,\text{ref}}$ is the yield of the standard sample measured under the same conditions. An alternative conventional method to estimate the absolute areal density is to make use of the signal of substrate material, Equation (27)

$$n_i = N_{i,t} = \frac{Y_i \delta E_{\text{ch}}}{[S]_i} N_{i,\text{ref}} \left( \frac{\sigma/d\Omega}_i \right) \approx \frac{Y_i \delta E_{\text{ch}}}{[S]_i} N_{i,\text{ref}} \left( \frac{Z_i}{Z_i^\text{ref}} \right)^2$$  \hspace{2cm} (27)

where $y_s$ is the height of the energy spectrum at the leading edge of the substrate, $\delta E_{\text{ch}}$ the corresponding energy for one channel, $N_{i,\text{ref}}$ the atomic density of the substrate, $(\sigma/d\Omega)_i$, the differential cross-section of the substrate atom and $[S]_i$ the energy-loss factor for the substrate.

### 3.3 Depth Profiling

When the stoichiometry changes with depth, the variation of the composition can be determined from the RBS spectrum. The stoichiometry at a depth $t$ can be derived from the corresponding yields of all compositional elements at $t$, Equation (28). In Equation (28) $F_i$ is the atomic fraction of element $i$ at a depth $t$.

$$F_i = \frac{y_i[S]_i \left( \frac{\sigma}{d\Omega} \right)_i}{\sum_j y_j[S]_j \left( \frac{\sigma}{d\Omega} \right)_j} \approx \frac{y_i[S]_i}{Z_i^2} \left( \frac{Z_i}{Z_i^\text{ref}} \right)^2$$  \hspace{2cm} (28)

This procedure is not simple because the energy-loss factor $[S]_i$ is a function of the composition. For dilute concentrations of an impurity, the stopping power is simply determined by the matrix and the depth profiling.
Figure 7 RBS spectrum of 2-MeV He ions backscattered from Si implanted with $1.2 \times 10^{15}$ As ions cm$^{-2}$ at 200 keV. The arrows indicate the energy of ions scattered from surface Si and As atoms. (Reproduced by permission of Plenum Press from Mayer et al.\textsuperscript{2})

is straightforward. Figure 7 shows an example of such an RBS spectrum for Si implanted with $1.2 \times 10^{15}$ As ions cm$^{-2}$ at 200 keV measured with 2-MeV He ions.\textsuperscript{2} There is a separated peak of As at ca. 1.55 MeV which corresponds to $t$ ca. 150 nm. The width of the As peak at ca. 60 keV is much larger than the energy resolution of the SSB detector showing that the observed As peak profile reflects the actual As distribution in Si. The energy-loss factors for Si and As are calculated to be 44.3 and 46.0 eV Å$^{-1}$ respectively. Using the peak yield of As, $y_{\text{As}} = 250$ and the Si yield at the corresponding depth, $y_{\text{Si}} = 28000$, the peak concentration can be calculated from Equation (28) as Equation (29)

$$F_{\text{As}} \approx \frac{250 \times 46/33^2}{(250 \times 46/33^2 + 28000 \times 44.3/14^2)} = 0.0017$$

Note that the sensitivity of RBS can easily reach 100 ppm level for heavy elements.

The RBS spectrum shown in Figure 7 also provides a good example of how to estimate areal density of the implanted atoms using Equation (27). Using the total yield of the As peak $Y_{\text{As}} = 3350$ and $\delta E_{\text{ch}} = 5$ keV, the areal density of As is given by Equation (30)

$$n_{\text{As}} \approx \frac{3350 \times 5}{28000 \times 44.3 \times 14.994 \times 10^{-2}} \times \frac{14^2}{33} = 0.12 \text{ Å}^{-2}$$

The value obtained agrees well with the number of implanted As ions measured in the implantation procedure. This good agreement clearly shows the capability for quantitative analysis in RBS.

3.4 Computer Simulation

When the signals from different elements overlap in a spectrum, derivation of the target composition as a function of depth is not straightforward although a basic derivation can be obtained using Equation (28). A powerful approach to analyzing RBS spectra is by computer simulation. There are a number of computer simulation programs to analyze the RBS spectrum such as RUMP,\textsuperscript{21} GISA,\textsuperscript{22} and SCATT/HYPRA.\textsuperscript{23} In these programs, the target composition is changed until the calculated spectrum matches the measured spectrum. As with other inverse problems, this procedure may obtain a local minimum. Recently, a simulated annealing algorithm was successfully applied to the analysis of RBS spectra.\textsuperscript{24} It tends asymptotically to the absolute minimum rather than to a local minimum with any initial compositions. This allows fully automatic analysis without time-consuming human intervention. Figure 8 shows examples of the different steps of the fit to a RBS spectrum of a multilayered iron–cobalt silicide generated by the simulated annealing algorithm. The final result agrees reasonably well with the original spectrum with a simple initial composition (Figure 8a) generated automatically by the program.

3.5 Channeling Effect

The energy spectrum from a single crystal aligned with a low-index axis or plane parallel to the incident beam direction is very different from those discussed before. The ion experiences a series of correlated small angle collisions with crystal atoms and cannot approach to the atomic row or plane over a certain distance. This phenomenon, called channeling, drastically reduces the yield of Rutherford scattering. The analyzing procedures described in the previous sections cannot be applied to the RBS spectra measured under channeling conditions. In a simple RBS measurement, a single crystal target is usually rotated during measurement to avoid channeling effects.

Although the channeling is undesirable for RBS, it provides a unique method for studying lattice defects.
Channeling ions might stop channeling upon scattering by lattice defects (dechanneling) or even be directly backscattered from the defects (direct scattering). These effects depend on the structure of the defect. Impurity atoms, for example, may cause direct scattering depending on both the location of the impurity atom and the channeling axis as shown in Figure 9.\(^{25}\) The substituted atoms cannot be seen by channeling ions but the interstitial atoms may be seen by the ions channeling through particular channels. Thus the site of the impurity atom can be roughly determined by channeling measurements at several major axes. For more detailed information, the lattice site of the interstitial atom can be determined within an accuracy of 0.01 nm by measuring the incident-angle dependence of the backscattering yield from the impurity atoms around the channeling direction.

Other defects also cause dechanneling and the energy dependence of the dechanneling probability is different in each case, that is \(\propto \sqrt{E}\) for dislocation, \(\propto E^0\) for stacking fault, and \(\propto E^{-1}\) for point defect.\(^{26}\) Thus the type of major defect can be determined by measuring the energy dependence of the dechanneling probability. Other useful applications of channeling are described in the literature.\(^{27-29}\)

### 3.6 Comparison to Related Techniques

The low-energy version of RBS is called ion scattering spectroscopy (ISS).\(^3\) Rare gas ions with energy of several kiloelectron volts and electrostatic analyzers are commonly used. ISS is sensitive to surface atoms because of the large neutralization probability of ions scattered from subsurface atoms and that is used extensively for compositional and structure analysis of surfaces. In order to study subsurface regions, the TOF technique is employed to measure energy spectra of both ions and neutral atoms. An alternative method is the use of alkali
metal ions for which the neutralization probability is small even for the ions scattered from the subsurface region.\(^{(30)}\)

The sensitivity of RBS is not sufficient for determination of trace elements. Particle-induced X-ray emission (PIXE) provides quantitative analysis of trace elements present at parts per million levels.\(^{(31)}\) Also see the article PIXE (Particle-induced X-ray Emission) in this publication. H ions of 1–3 MeV are used to produce inner-shell vacancies in target atoms. Characteristic X-rays emitted via refilling the inner-shell vacancies by outer-shell electrons are detected by an X-ray detector. Compared with the similar technique of electron probe microanalysis (EPMA), the background due to the bremsstrahlung is many orders of magnitude smaller and a sensitivity of better than 0.1 ppm is easily obtained for many elements in low-mass materials. Although the sensitivity of PIXE is excellent, PIXE does not have depth resolution.

Elastic Recoil Detection (ERD) is a similar technique to RBS.\(^{(32)}\) Also see the article Elastic Recoil Detection Analysis in this publication. In ERD, recoiled ions are detected instead of the scattered ions. While RBS is suitable for analysis of heavy elements, ERD provides quantitative depth profiles of light elements, especially hydrogen. Before the first introduction of ERD,\(^{(33)}\) nuclear reaction analysis (NRA) was predominantly used to measure depth profiles of light elements.\(^{(34)}\) Also see the article Nuclear Reaction Analysis in this publication. Nowadays, ERD is commonly used because of its simplicity and ease of use although the standard ERD has poorer sensitivity and depth resolution than NRA.

4 ADVANCED TECHNIQUES

4.1 Heavy Ion Rutherford Backscattering Spectroscopy

As was discussed in section 2.1, use of heavy ions improves mass resolution. Heavy ions also have an advantage of better depth resolution than light ions because the stopping power is proportional to the square of the ion charge. Figure 10 shows an example of heavy ion RBS (HIRBS) spectrum of a thin Y\(_1\)Ba\(_2\)Cu\(_3\)O\(_7-x\) film using 22-MeV \(^{12}\)C ions and a SSB detector.\(^{(35)}\) Although the energy resolution of the SSB detector is degraded for C ions, the separation of each element is perfect and, moreover, two copper isotopes, \(^{63}\)Cu and \(^{65}\)Cu, are clearly resolved, which is usually impossible in the standard RBS with megaelectron-volt He ions.

If the TOF technique is employed to measure the energy spectrum instead of the SSB detector, the energy resolution and thus both the mass and depth resolutions are improved considerably (typical energy resolution of TOF detectors is better than 1\%). Figure 11 depicts an example of a HIRBS spectrum (25 MeV \(^{35}\)Cl beam) of a 48 nm layer of GaAs capped by a 26 nm Pd layer on Si substrate measured with a TOF detector.\(^{(36)}\) The two Ga isotopes as well as several Pd isotopes are well-resolved.

Although the excellent mass resolution is clear in HIRBS, there are several disadvantages of HIRBS: (1) The cross-section deviates from the Rutherford formula particularly for heavy target elements. (2) Light
elements are less sensitive than standard RBS; in particular, elements lighter than the probe ion cannot be analyzed. (3) Irradiation of heavy ions causes significant radiation damage not only in targets but also in the SSB detectors.

4.2 High-resolution Rutherford Backscattering Spectroscopy

Improvement in the depth resolution up to atomic level has been tried by several groups. An overview of existing high-resolution spectrometers for IBA is given in the literature. It was shown that both a high-resolution spectrometer (energy resolution of ca. 0.1% is easily achieved for electrostatic or magnetic spectrometers) and a grazing-angle technique are essential for monolayer resolution in RBS. Figure 12 shows examples of HRBS spectra of PbTe (100) and PbTe (111) measured with a magnetic spectrometer. The arrows labeled Pb and Te indicate the energies of the ions elastically scattered from Pb and Te atoms. There are several peaks at ca. 285.5, ca. 283.3 and ca. 281.1 keV in Figure 12(a). These peaks correspond to the Pb atoms in the first, second, and third atomic layers, respectively. Note that even the ions scattered from the topmost atomic layer show inelastic energy loss because the electronic surface is outside the atomic surface. There are also small peaks at ca. 278 and ca. 275.8 keV corresponding to the Te atoms in the first and second layers. The yield ratio of the Pb peak to the Te peak is close to the cross-section ratio indicating that the PbTe (100) is stoichiometric. The spectrum of PbTe (111) shown in Figure 12(b) is basically the same as the PbTe (100) except for the yield of the first Pb peak. The yield of the first Pb peak is about 25% of the second and third Pb peaks and the inelastic energy loss for the first Pb peak (ca. 1 keV) is smaller than that for the first Te peak (ca. 2.1 keV). From these results, it can be concluded that the PbTe (111) surface is terminated by the Pb layer and the atomic density of the topmost Pb layer is reduced to about 25% of the bulk value.

Combination of heavy ions with a high-resolution spectrometer may provide better depth resolution. In addition to the large radiation damage, however, the charge-state distribution of the scattered heavy ions complicates the analysis because the scattered ions of all charge states cannot simultaneously be measured by the electrostatic or magnetic spectrometers. An optimal probe ion for HRBS has been discussed and

![Figure 11](image1.png)

the sub-megaelectron-volt He ion was concluded to be the best one.\(^{(46)}\)

Disadvantages of HRBS are the relatively small acceptance angle \(\Delta \Omega\) (typically less than 1 mrad) and a narrow energy window of the spectrometer (typically several percent of the ion energy). These lead to a long acquisition time and possible radiation damage. Spectrometers with a wide acceptance angle and a wide energy window have been developed by several groups\(^{(47,48)}\) and not only a high-resolution spectrometer but also a high-resolution RBS system with a compact sub-megaelectron-volt ion accelerator are now commercially available.

4.3 Microprobe Rutherford Backscattering Spectroscopy

Finely focused high-energy ion beams turn ion beam spectroscopy into ion beam microscopy.\(^{(49)}\) Development of a high-energy ion microprobe was started as early as the late 1960s. There are more than 40 facilities which have high-energy ion microprobes. Magnetic quadrupole lenses are commonly used to form microprobes of the order of 1 \(\mu\)m at a beam current of ca. 100 pA. In scanning the microprobe across a specimen and detecting a variety of ion-scattering processes, such as RBS, PIXE elastic recoil, nuclear reaction, and so on, microscope images are obtained. These images display features of the specimen that cannot readily be imaged by other techniques. The combination of the microprobe with RBS provides three-dimensional mapping of elements in the specimen.

Figure 13 shows an example of the RBS mapping and tomographic image of 1-\(\mu\)m-sized WSi\(_x\) lines.\(^{(50)}\) A beam of 300-keV Be\(^{2+}\) ions (beam size ca. 0.1 \(\mu\)m) was rastered over a 30 \(\times\) 30 \(\mu\)m\(^2\) area and RBS spectra were measured at 128 \(\times\) 128 points. The mapping image is made with the W signal of the observed RBS spectra. The tomographic image shows the cross-sectional image along the line shown in the mapping image, which is obtained by converting the each RBS spectrum to a depth distribution of W. The WSi\(_x\) lines are clearly resolved in both the mapping and the tomographic images.

4.4 Light Element Analysis by Non-Rutherford Scattering

When the ion energy approaches the Coulomb barrier height of the target nucleus, the ion penetrates the Coulomb barrier and a compound nucleus in a highly excited state may be formed. If the incident energy of the ion matches one of the excited levels, the reaction probability is considerably changed and often enhanced. The excited compound nucleus thus produced may decay via re-emission of the incident particle. This phenomenon, called elastic resonance scattering, has a large cross-section sometimes several orders of magnitude larger than the Rutherford cross-section. Figure 14 displays an example of the non-Rutherford cross-section for \(^{4}\)He–\(^{16}\)O scattering as a function of the incident He energy.\(^{(51)}\) There are several resonances with enhancement factors of 100–200. Because the cross-sections for heavy elements remain Rutherford values in this energy region, the relative sensitivity for oxygen is improved by a factor of ca. 100. However, the cross-section varies in a very complicated manner with energy and also with the scattering angle. The analysis of energy spectra has to be performed with care. There is an energy region, 8.3–8.9 MeV, where the cross-section varies slowly. Using this energy region the analysis of oxygen is as simple as standard RBS with an enhancement factor of about 35.

![Figure 13](image1.png)

RBS Mapping Image

Tomographic Image

**Figure 13** RBS mapping and tomographic image of 1-\(\mu\)m-sized WSi\(_x\) lines measured with a microprobe. (Reproduced by permission of Elsevier Science B.V. from Park et al.\(^{(50)}\))

![Figure 14](image2.png)

**Figure 14** Measured 170° laboratory cross-sections for \(^{4}\)He–\(^{16}\)O expressed in terms of the Rutherford cross-sections. (Reproduced by permission of Elsevier Science B.V. from Cheng et al.\(^{(51)}\))
A sharp and isolated resonance is seen at $E_R = 3.045$ MeV. When the energy of the incident He ions is larger than $E_R$, the resonance occurs at a certain depth where the ion energy matches $E_R$ after energy loss in the incoming path, that is, only the oxygen at a certain depth can be seen by the resonance. Thus a sharp resonance can be used for depth profiling of oxygen by sweeping the incident ion energy. Other examples of sharp resonances used in non-RBS are the 4.265 MeV resonance in the $^4\text{He}/^1\text{H}$ cross-section and 2.525 MeV resonance in the $^1\text{H}/^9\text{Be}$ cross-section. Useful data on non-Rutherford cross-sections for H and He incident ions are compiled in the literature.\(^{52}\)

1 Introduction

The interactions of γ-radiation and neutrons with matter form the basis of a large number of nuclear techniques developed for chemical analysis or used to infer properties of interest in logging. Nuclear techniques have the ability to measure properties of materials without contact and, because of the high penetration of both γ-radiation and neutrons, enable measurements to be made through walls. In borehole-logging applications, these two types of penetrating radiation can traverse the pressure housing of the logging tools and the formation and return a signal carrying information about the surrounding formation and the rock matrix.

This article presents the principles of the interaction of γ-rays and neutrons with matter and outlines geological/mineral applications. The emphasis is on nuclear borehole logging. Because of the deep penetration of neutrons and γ-rays, nuclear techniques are well suited to borehole-logging applications. The volume of matter investigated by nuclear radiation is much larger than the core analyzed from a cored borehole, so a more representative sample is analyzed.

Well logging grew from the need of the petroleum industry to evaluate hydrocarbon formations. Today, borehole logging is a mature technology, and nuclear logging is well established in the oil, gas, uranium and coal industries. It is also making inroads in the mineral industry. It is now very difficult to imagine these industries without logging.

Nuclear logging, employing in situ γ-ray spectroscopy, can measure the chemical composition of the earth formation, thereby providing an indication of the dominant mineralogy. This is vital information in oil well logging. In situ γ-ray spectroscopy replaces the time-consuming chemical analysis of the core in a laboratory. Bulk density, which is another important property of an earth formation, is measured by γ-ray scattering. Some minerals contain the natural radioactive elements potassium, thorium and uranium. The detection of their γ-radiation indicates the presence of these elements, and quantitative measurements can be made of their concentration.

Nuclear applications are an integral part of today’s measurement technologies, contributing to increased applications, including well logging, bulk analysis and on-stream analysis. The first part of this article presents the physics of the interaction of γ-rays and neutrons with matter. Applications based on these interactions to well logging for oil, uranium, coal and iron ore are presented in the second part of the article. Applications based on the natural radioactivity of rocks are also covered.
efficiency and large financial savings in industry. Although
a mature technology, new applications are still being
found.

2 SCATTERING CROSS-SECTION

For the study of neutron and γ-ray scattering it is
convenient to introduce the scattering cross-section. For
a very thin target bombarded with neutrons or γ-rays,
the number of scattered particles is very small compared
with the number of particles in the beam, as shown in
Equation (1):

\[-\frac{dN}{N} = \sigma A \, dx = n \sigma \, dx\]  (1)

where \(-dN\) is the number of scattered particles, \(N\) is
the number of incoming particles, \(dx\) is the thickness of
the target and \(A\) is a proportionality constant dependent
on the number of nuclei per unit volume \(n\) and the
nature of the nuclei, represented by \(\sigma\), the scattering
cross-section. For a thicker target, the number of particles
passing through undeflected, \(N\), is obtained by integrating
Equation (1), illustrated in Equation (2):

\[N = N_0 \, e^{-n \sigma x}\]  (2)

where \(N_0\) is the total number of particles in the beam
which hit the target. The total number of particles scattered
from the beam is shown in Equation (3):

\[N_{sc} = N_0 (1 - e^{-n \sigma x})\]  (3)

When the target contains several isotopes of different
cross-sections, \(n \sigma\) is replaced by \(n_1 \sigma_1 + n_2 \sigma_2 + n_3 \sigma_3 + \cdots\)

3 SCATTERING AND ABSORPTION OF
γ-RADIATION

γ-Rays are electromagnetic radiation, as are X-rays, light,
radio waves, etc. For γ-rays or neutrons, the processes
by which they interact with matter are such that a single
event will remove the γ-ray or neutron from the beam.
According to Equation (2), the intensity of the beam
hitting a target will decrease exponentially, as illustrated
in Equation (4):

\[N = N_0 \, e^{-n \mu x}\]  (4)

where the constant \(\mu\) is called the absorption coefficient
and has dimension (length)\(^{-1}\). It is also common to mea-
sure absorber thickness in \(\text{g cm}^{-2}\) and write Equation (4)
as Equation (5):

\[N = N_0 \, e^{-\mu x}\]  (5)

where \(\xi = \rho x\) is the mass per unit area and where
the mass absorption coefficient \(\mu_m\) is, as illustrated in
Equation (6):

\[\mu_m = \frac{\mu}{\rho} = \frac{n \sigma}{\rho} = \frac{N_A \sigma}{M_A}\]  (6)

\(N_A\) is Avogadro’s number, \(M_A\) is the atomic weight of
the element in the absorber and \(\rho\) is the density. If more
elements are present in the absorber, then Equation (7)
applies:

\[\mu_m = N_A \sum_i \frac{\alpha_i \sigma_i}{M_{Ai}}\]  (7)

where \(\alpha_i\) is the abundance ratio of the \(i\)th element.

The interaction of γ-radiation with matter in the energy
range from 50 keV to 50 MeV is dominated by three
processes: (1) photoelectric effect, (2) Compton effect
and (3) pair production.

3.1 The Three Principal Processes

3.1.1 The Photoelectric Effect

In the photoelectric effect, predominant at low energies,
the γ-ray (photon) gives all its energy to a bound electron.
The electron, to overcome its binding energy in the atom,
uses part of the energy and the rest is taken as kinetic
ergory. The energy of the emitted electron is therefore
\(E_e = E_\gamma - E_b\), where \(E_\gamma\) is the γ-ray energy and \(E_b\)
the binding energy of the electron in the atom, usually the
k-shell energy. The probability of photon interacting with
an electron in a given orbit is higher when the energy of
the photon is equal to the binding energy and decreases
with increasing energy. The electron gives up its energy
to other atoms and eventually falls back into an orbit. The
X-rays emitted following the capture of the electrons into
orbits interact with the matter again and again until all
the energy is absorbed either at very low-energy orbital
levels or other mechanisms which are outside the scope
of this article.

The cross-section of the photoelectric absorption per
atom is a function of photon energy, \(E\), illustrated in
Equation (8), and is approximated\(^{1}\) as being propor-
tional to:

\[\sigma(E) \approx \frac{Z^{4.5}}{E^n}, \quad 2.5 \leq n \leq 3.5\]  (8)

The mass absorption coefficient for the photoelectric
effect is shown in Equation (9):

\[\mu_{mph} = \rho N_A \sum_i \frac{\alpha_i \sigma_i(E)}{M_{Ai}}\]  (9)

The contribution of the photoelectric effect at low
energies is significant for heavy elements because of
their high atomic number. For lighter elements, the contribution of the photoelectric effect is reduced as a result of the linear relationship between its cross-section and $Z^4$.

3.1.2 The Compton Effect

The Compton effect predominates around 1 MeV. It implies scattering of photons by the atomic electrons. The photon is deflected from its trajectory with or without loss of energy, as shown schematically in Figure 1 ($\nu$ is the frequency of the photon of wavelength $\lambda$, where $\nu = 1/\lambda$). This happens at photon energies much larger than the electron binding energies so that, theoretically, the electrons can be considered free. Expressions for the energy $h\nu'$ of the scattered photon, the energy $T$ of the scattered electron and the relationship between the angles of scattering shown in Figure 1 are given in Appendix 1. The cross-section for the Compton scattering was calculated by Klein and Nishina. It is well described by Davisson and many other books of nuclear physics or quantum mechanics.

3.1.3 The Pair Production Effect

In the pair production effect, a photon disappears with the creation of an electron/positron pair. The total kinetic energy of the resultant particles is equal to the photon energy minus the mass energy of the electron/positron pair created by the interaction (1.02 MeV) and therefore the pair production effect cannot take place below 1.02 MeV. Figure 2 shows schematically the pair production effect. The pair production takes place in the field of a nucleus or electron with no change of the state of the nucleus or its electrons. The nucleus must be present to absorb some of the momentum of the photon. Pair production cannot take place in the absence of the nucleus or electron because the conservation of energy and conservation of momentum cannot be simultaneously observed.

3.2 Other Interactions of $\gamma$-Rays With Matter

The photoelectric, Compton and pair production effects are the major interactions of $\gamma$-rays with matter and contribute most of the total $\gamma$-ray attenuation coefficient in the energy region being considered. However, they are not the only interactions. Other interactions of interest are resonance scattering of $\gamma$-rays and photonuclear reactions, also called $\gamma$-activation. There are other interactions (Thomson, Delbrück, Rayleigh) which occur at low energies. They are treated in more specialized books and are outside the scope of this general article.

3.2.1 Resonance Scattering

$\gamma$-Ray resonance scattering is an elastic process that takes place via an excited state of a stable nucleus. If the energy of the $\gamma$-ray corresponds exactly to the energy level of the stable nucleus, the nucleus can absorb this $\gamma$-ray and become an unstable excited nuclear state. The nucleus will regain its stable state by emitting a $\gamma$-ray that is theoretically of the same energy as the one absorbed. In practice, the $\gamma$-ray emitted by the excited nucleus at rest has less energy than the photon that excited the nucleus, $E_r$, because of the recoil energy taken by the nucleus. If $M$ is the mass of the emitting atom, conservation of energy and momentum leads to the expression for the energy of the emitted photon $h\nu$: $h\nu = E_r - (E_r^2/2Mc^2)$. The same amount of kinetic energy is transferred to the nucleus which is excited by the $\gamma$-ray, so that the total energy displacement is $\Delta E = E_r^2/Mc^2$. In general, $\Delta E$ is large by comparison with the width of the energy level $\Gamma$ and the system is out of resonance, in other words
the cross-section for resonance absorption is small. From Heisenberg’s principle, \( \Gamma(eV) = 6.58 \times 10^{-16}/\tau \), where \( \tau \) is the lifetime of the excited state in seconds. This is why it took a long time to prove the existence of \( \gamma \)-ray resonance scattering.

Mössbauer discovered that an atom embedded in a crystal lattice can emit or absorb \( \gamma \)-radiation without loss from the recoil because the momentum is taken up by the crystal as a whole with negligible energy loss.

There are a few methods of producing resonance scattering. The change of quantum energies can be achieved by moving the absorber and the radiation source with respect to each other (based on the Doppler effect). Another practical technique to obtain \( \gamma \)-rays of the precisely defined energy for resonance scattering is to choose a radioisotope source that decays via the excited state of the chosen element. For example, if the element chosen for \( \gamma \)-ray scattering is \( ^{60}\text{Ni} \), a \( ^{60}\text{Co} \) source may be used. \( ^{60}\text{Co} \) decays by \( \beta^- \) and \( \gamma \)-ray emission via excited states of \( ^{60}\text{Ni} \). Matching the radioactive source to the chosen element is essential for \( \gamma \)-ray resonance. Resonance scattering does not take place when the \( \gamma \)-ray source is in a solid state because the recoil energy losses during the emission of \( \gamma \)-rays make it difficult in energy by several tens of keV. This deficiency may be overcome by using a gaseous source. \( \gamma \)-Rays from gaseous sources are Doppler broadened so that about 1% of the \( \gamma \)-rays are in resonance.

\( \gamma \)-Ray resonance scattering has found practical applications. Mössbauer spectroscopy is a powerful technique for elemental analysis based on this effect. Copper and nickel are two favorable elements for analysis by \( \gamma \)-ray scattering

3.2.2 Photonuclear Reactions

\( \gamma \)-Rays of high energies can produce nuclear reactions with atomic nuclei. If the incident \( \gamma \)-ray energy exceeds a threshold energy, it is possible to remove particles from stable nuclei. Each element is characterized by a particular threshold energy. The most frequent nuclear reactions induced by high-energy \( \gamma \)-rays in the energy range of interest are \( (\gamma,n) \) processes. The maximum cross-section for light elements is at 20–25 MeV and \( \cong 15 \) MeV with other elements. The photonucleon reaction has found practical applications mostly for the determination of low-atomic-number elements. The technique is selective if the \( (\gamma,n) \) threshold energies are selected appropriately.

The only reactions to have threshold energies less than 2.5 MeV are the \( (\gamma,n) \) reactions for \( ^9\text{Be} \) (threshold = 1.67 MeV) and \( ^3\text{H} \) (2.22 MeV). The \( (\gamma,n) \) reaction with beryllium has been used in different techniques of analysis for this element. \( ^{124}\text{Sb} \) is a suitable \( \gamma \)-ray source for beryllium analysis. It has a half-life of 60 days and emits \( \gamma \)-rays of 1.69 and 2.09 MeV. The average energy of neutrons from the \( ^9\text{Be}(\gamma,n) \) reaction using a \( ^{124}\text{Sb} \) source is approximately 24 keV. The neutrons are moderated in a hydrogenous moderator and detected with thermal neutron detectors such as \( ^{10}\text{BF}_3 \) or \( ^3\text{He} \) counters.

3.3 Density and Composition Measurements

With \( \gamma \)-Rays

The three major interactions of \( \gamma \)-radiation with matter have found wide industrial applications. Here we review the basis of density and composition determination.

The Compton mass attenuation coefficient \( \mu_c \) for photon energies much larger than the electron binding energies can be expressed as (Equation 10):

\[
\mu_c = \frac{\rho N_A Z}{M_A} e_\mu
\]  

(10)

where \( \rho N_A/M_A \) represents the number of atoms per cubic centimeter, \( Z \) is the number of electrons in the atom and \( e_\mu \) is the Compton scattering cross-section per electron. For a \( \gamma \)-ray of given energy (Equation 11):

\[
\mu_c = \frac{Z}{M_A} \rho
\]  

(11)

Except for hydrogen, the \( Z/M_A \) ratio for low-\( Z \) elements (which form the Earth’s crust) is very nearly a constant equal to \( \frac{1}{4} \). For hydrogen, \( Z/M_A = 1 \), and this introduces an error when hydrogenous material is present in matter investigated. If the energy of \( \gamma \)-rays is greater than 300 keV, one can neglect the photoelectric effect and assume that the interaction is by the Compton effect. Equation (4) can be used to derive Equation (12):

\[
\log N = \log N_0 - \mu_c x = \log N_0 - \frac{Z}{M_A} \rho x
\]  

(12)

For a radioactive source of long half-life, \( N_0 \) is constant. By plotting a graph of \( \log N \) vs density (\( \rho \)), one obtains a straight line if the thickness \( x \) of the materials of different densities is constant. The density is extracted from this linear relationship.

Concept of Equivalent Atomic Number, \( Z_{eq} \). In order to facilitate measurement of the chemical composition of a medium by \( \gamma \)-scattering, Czubek(1) introduced a quantity called the equivalent atomic number (\( Z_{eq} \)) of the scattering medium in terms of photoelectric and Compton coefficients. We have seen that the Compton and photoelectric absorption coefficients \( (\mu_c, \mu_{ph}) \) for given \( \gamma \)-ray energies are proportional to \( (Z/M_A) \rho \) and \( (Z^{1/3}/M_A) \rho \) respectively. Therefore, \( \mu_{ph}/\mu_c = \text{const.} Z^{3/5} \). One can
show that, for a mixture of elements (Equation 13):

$$Z_{eq} = Z = \frac{\sum_{i} W_i Z_i^{1.5}}{\sum_{i} W_i M_{Ai}^{1.5}}$$

(13)

where $Z_{eq}$ is a substitute for $Z$ for a multielement medium. With the assumption that $Z_i/M_{Ai}$ is a constant for low-$Z$ elements,

$$Z_{eq} = \sum_{i} W_i Z_i^{1.5}$$

(14)

Equation (14) shows the strong dependence of the $Z_{eq}$ of a medium on the constituent element with the highest atomic number. This dependence can be used to determine the concentration of a high-$Z$ element in a matrix of low-$Z$ elements, e.g. the percentage of Fe in iron ore, ash in coal, etc. (%Fe or %ash are proportional to $Z_{eq}$).

**Practical Methods of Density and $Z_{eq}$ Measurements**

When there is access to both sides of the medium under investigation, the density and $Z_{eq}$ are determined by measuring the direct attenuation of $\gamma$-radiation passing through the medium. A collimated $\gamma$-ray beam of energy greater than 300 keV is employed for density measurements. The $\gamma$-ray sources used are usually $^{60}$Co and $^{137}$Cs. By using $\gamma$-rays of both low energy and high energy in a medium with a high photoelectric absorption coefficient, one can determine both the photoelectric and Compton absorption coefficients of the medium and thus $Z_{eq}$ from Equation (13).

When only one side of the medium is available, e.g. boreholes, roads or thick walls, the detector and the source are placed on the same side of the medium. Shielding is used to stop the $\gamma$-rays from the source reaching the detector. Figure 3 shows schematically the geometry suitable for this application together with the $\gamma$-ray energy spectrum recorded by the detector. The $\gamma$-rays from the source undergo successive Compton scattering, losing energy. The $\gamma$-rays can reach the detector after one or multiple scatterings. Below 300 keV the photoelectric absorption increases with decreasing $\gamma$-ray energy. This spectrum is called the backscattered spectrum. It ranges from almost the source energy down to an energy at which photoelectric absorption reduces the spectral intensity to almost zero. The high-energy region of the spectrum, above 300 keV, is a function of the electronic density of the medium, and below 300 keV both photoelectric and Compton effects are present. Theory shows that the ratios of the count rates recorded in two energy windows, at high and low energy, is a function only of the $Z_{eq}$ of the medium. Borehole logging techniques for the determination of Fe grade in iron ore deposits or ash in coal have been developed on this basis.45,5

4 NATURAL $\gamma$-RADIATION

All rocks and soils contain a great number of radioactive elements that emit $\gamma$-radiation. The three main sources of natural $\gamma$-rays are potassium, decay products in the uranium series and decay products in the thorium series.

Of the three naturally occurring isotopes of potassium, only $^{40}$K is radioactive; it has a half-life of $1.28 \times 10^9$ years and isotopic abundance of 0.0118%, which gives a specific activity of 31.4 Bq per g of natural potassium. $^{40}$K decays to $^{40}$Ca and emits a $\gamma$-ray of energy 1.46 MeV. Because many rock-forming minerals contain potassium, it is the commonest natural $\gamma$-ray encountered in nature.

$^{238}$U and $^{235}$U are more abundant among the isotopes of uranium, with $^{238}$U making up 99.3% of the total. Each isotope of uranium decays by $\alpha$-emission to an isotope of thorium. Thorium and its daughters are also radioactive and a decay chain of the parent isotope is produced. $^{238}$U has a half-life much longer than its radioactive decay products, and in an undisturbed medium a secular equilibrium is established. A radioactive decay series is said to be in a state of secular equilibrium when the number of atoms of each daughter being produced in the series is equal to the number of atoms of that daughter being lost by radioactive decay. $^{214}$Bi is one of the isotopes produced in the $^{238}$U chain and decays emitting a 1.765 MeV $\gamma$-ray. This $\gamma$-ray can be used for the determination of uranium concentration in a uranium deposit if the deposit is in equilibrium. Uranium is widespread in the environment. Most crustal rocks contain some uranium, averaging about 2.7 ppm or 33 Bq kg$^{-1}$. Phosphate-bearing rocks used as fertilizer contain high concentrations of uranium. It is also found in high concentration in oceans, ranging from about 2 to 3.7 mg m$^{-3}$.

$^{232}$Th has a decay chain similar to the decay chains of uranium. One prominent $\gamma$-ray of energy 2.6 MeV, emitted by the daughter product $^{208}$Tl, is usually used for the determination of thorium concentration. Like uranium, thorium is widely found in rocks. The average thorium content of the continental upper crust is 9–10 ppm, about four times greater than that of uranium. However, having lower activity than uranium, the radioactivity concentration of thorium and uranium is about the same. High concentrations of thorium (≥10%) are found in monazite, a rare-earth mineral. Owing to its high level of radioactivity, people living close to monazite sands can be exposed to high doses of radiation.

Measurement of natural radiation has found many applications. Because of the high level of natural
radioactivity in shales it is used to distinguish between shales and other sediments. It is also used in the exploration and mining of uranium. A technique to determine the ash content of coal on conveyor belts has also been developed. It is based on the fact that uranium, thorium and potassium are associated with the mineral matter in coal and the $\gamma$-ray activity of coal is correlated with the ash content.\(^6\) An interface gauge for the simultaneous monitoring of the green liquor and red mud interface and the profile of the solids concentration has been developed for the alumina industry. It has been shown that, subsequent to the digestion of bauxite in caustic soda, traces of radioactivity originally present in bauxite remain with the red mud and the green liquor is free of radioactivity.\(^7\) The gauge consists of a number of $\gamma$-ray counters arranged inside a Teflon-coated steel tube, which is suspended vertically inside settling tanks.

5 SCATTERING AND ABSORPTION OF NEUTRONS

The neutron is a neutral particle having a mass approximately equal to the mass of a proton (about 1800 times the rest mass of an electron). The neutron has a magnetic moment and therefore there is an electromagnetic...
interaction between the neutron and the atomic electrons. However, this interaction is small and can be neglected when studying the scattering and stopping of neutrons in matter. In the present discussion we will assume that the neutron interacts exclusively with the atomic nuclei. Consequently, neutron interactions in matter are rarer than γ-ray interactions and neutron ranges are longer.

The neutron energies are arbitrarily classified as:

- fast neutrons – above 500 keV
- intermediate – 1 keV to 500 keV
- slow – below 1 keV.

Slow neutrons are further subdivided as

- epithermal neutrons – from 0.1 eV to 1 keV
- thermal neutrons – below 0.1 eV.

5.1 Neutron Sources

The most common neutron sources used in applications are: (1) isotopic sources, (2) neutron generators and (3) nuclear reactors.

5.1.1 Isotopic Sources

Isotopic sources use (i) (α,n) reactions, (ii) photo-neutron reactions or (iii) the fission process.

Neutron Sources Based on the (α,n) Reaction

The principal reaction leading to neutron emission is the reaction: $^9\text{Be} + \alpha \rightarrow ^{12}\text{C} + n$. This source consists of an α-emitting nuclide, e.g. Am, Pu, Po or Ra, mixed with beryllium. The α-emitter and the beryllium are usually in powder form and are doubly sealed in stainless-steel capsules.

Neutrons Emitted by Photonuclear Reactions

The binding energy of the last neutron in $^9\text{Be}$ is only 1.67 MeV, and neutrons can therefore be released from $^9\text{Be}$ by photodisintegration, i.e. by bombardment with γ-rays of energy 1.67 MeV or more.

Fission Sources

The spontaneous fission of $^{252}\text{Cf}$, which is an artificial isotope produced in nuclear reactors, is a source of neutrons. The Cf nucleus splits spontaneously into two fission products and emits one or more neutrons.

5.1.2 Neutron generators

Intense neutron radiation can be obtained by bombarding various targets with charged particles from a Van de Graaff accelerator or from a cyclotron. Commercially available neutron generators use one of the following reactions: $^2\text{H} + ^2\text{H} \rightarrow ^3\text{H} + n (\text{D–D reaction})$ or $^2\text{H} + ^3\text{H} \rightarrow ^4\text{He} + n (\text{D–T reaction})$. Neutron generators based on these reactions produce neutrons of energies 2.6 MeV and 14 MeV respectively.

5.1.3 The Nuclear Fission Reactor

The nuclear fission reactor provides neutron fluxes of high intensity close to the reactor core.

5.2 Interaction of Neutrons with Matter

A fast neutron suffers many interactions in the process of losing its energy to reach thermal energy. This process is called slowing down. The neutron may disappear during this process as a result of nuclear reactions when the neutron impinges on nuclei forming the scattering medium. The probability of scattering from or reaction with a single nucleus is called cross-section ($\sigma$). The unit for $\sigma$ is the barn and is equal to $10^{-24}$ cm$^2$.

There are four types of interactions that can occur between the neutron and the surrounding nuclei: (1) particle reactions (n,x), e.g. (n,α), (n,p), (n,xn) (for neutrons of high energy only), (2) inelastic scattering (n,n’γ) (the neutron energy must be above a threshold characteristic for each element, normally above 1 MeV), (3) elastic scattering and (4) radiative capture.

5.2.1 (n,x) Reactions

A nuclear reaction involves the release of a charged particle or more than one neutron. The final reaction product cannot be the same as the target nucleus. Characteristic γ-rays are emitted and the neutron reactions can be used to identify the presence of particular elements in materials or for the determination of their concentration.

5.2.2 Inelastic Scattering

A neutron can interact with a nucleus of atomic number Z and mass number A to form a compound nucleus in an excited state of mass A + 1. The compound nucleus decays very rapidly to the ground state by emitting a γ-ray, and it then emits a neutron. The γ-rays that are produced are characteristic of the energy levels of the compound nucleus and can be used to identify the target nucleus.

5.2.3 Elastic Scattering

Elastic scattering is the most important interaction for neutrons produced by isotopic sources (average energy below 4.5 MeV). This interaction is also known as “billiard ball” scattering. Although the neutron reactions and inelastic scattering reduce the neutron population, their importance is modest by comparison with neutron scattering. Inelastically scattered neutrons can suffer large
energy loss; however, they constitute a small fraction of the neutrons slowing down to low energies. Most of the neutrons reach low energies through repeated elastic collisions. In elastic scattering, a percentage of the incident neutron’s kinetic energy is transferred to the recoiling nucleus and the neutron will have less kinetic energy after collision.

A useful quantity in the theory of the neutron slowing-down process is the percentage decrease in the neutron energy as a result of a collision. This is usually expressed as the average logarithmic energy decrement, also known as neutron lethargy. For nuclei with mass $A > 10$, which are common in the Earth’s crust, $\xi = 2/(A + 2/3)$. For hydrogen $\xi = 1$. Typical values of $\xi$ for a few common nuclei are: H(1), C(0.158), O(0.12), Al(0.072), Si(0.070), Ca(0.049), Fe(0.035). The lethargy is used to calculate the mean number of scatterings required to slow down the neutron. For example, the average number of scatterings calculated for a few elements to slow down a neutron of 14 MeV, produced by a neutron generator, to thermal energy (0.01 eV) are: H(19), C(112), O(154), Al(290), Si(297), Fe(539). These examples show the unique position of hydrogen in slowing down neutrons. Its position is further enhanced when taking into account scattering cross-sections. Most of the nuclei abundant in the Earth’s crust have scattering cross-sections of several barns. The proton’s scattering cross-section between 10^5 eV and 0.5 eV is about 20 barn.

The cross-section for elastic scattering, the relationship between the neutron energies before and after scattering and the theoretical expressions for lethargy are given in Appendix 1.

5.2.4 Radiative Capture

Once slowed down to thermal energies, neutrons diffuse through the medium without further loss of energy until their life is terminated by other processes such as radiative capture. In this process, the thermal neutron enters the nucleus, producing a compound nucleus in an excited state, which then decays to the ground state by the emission of one or more $\gamma$-rays that are characteristic of the capture nucleus. The radiation capture process only takes about 10^{-11} s, which is virtually instantaneous compared with the initial slowing down and diffusion process, which may take several hundred microseconds. The product nucleus may be stable or it may decay (with a half-life of between a few microseconds and a number of years) to another product nucleus, often with $\beta$-particle emission. This is called thermal neutron activation.

5.3 Macroscopic Treatment of Slowing Down

For a moderating medium consisting of a homogeneous collection of different elements, the elastic macroscopic scattering cross-section $\Sigma$ can be written as $\Sigma = \int n_i \sigma_{si} \, dV$, where $n_i$ is the number of nuclei of the $i$th element per cubic centimeter and $\sigma_{si}$ represents the existing elements. The same applies to the absorption cross-section $\Sigma_A$. The neutron slowing-down process is the percentage decrease in the neutron density with distance.

A useful quantity in the theory of the neutron slowing-down process is the percentage decrease in the neutron energy as a result of a collision. This is usually expressed as the average logarithmic energy decrement $\xi$, also known as neutron lethargy. For nuclei with mass $A > 10$, which are common in the Earth’s crust, $\xi = 2/(A + 2/3)$. For hydrogen $\xi = 1$. Typical values of $\xi$ for a few common nuclei are: H(1), C(0.158), O(0.12), Al(0.072), Si(0.070), Ca(0.049), Fe(0.035). The lethargy is used to calculate the mean number of scatterings required to slow down the neutron. For example, the average number of scatterings calculated for a few elements to slow down a neutron of 14 MeV, produced by a neutron generator, to thermal energy (0.01 eV) are: H(19), C(112), O(154), Al(290), Si(297), Fe(539). These examples show the unique position of hydrogen in slowing down neutrons. Its position is further enhanced when taking into account scattering cross-sections. Most of the nuclei abundant in the Earth’s crust have scattering cross-sections of several barns. The proton’s scattering cross-section between 10^5 eV and 0.5 eV is about 20 barn.

The cross-section for elastic scattering, the relationship between the neutron energies before and after scattering and the theoretical expressions for lethargy are given in Appendix 1.

6 RADIATION DETECTORS

The $\gamma$-ray detectors most commonly used in nuleonic gauges can be divided into three categories: gas-filled counters, scintillation detectors and solid-state detectors. The gas-filled counter is one of the oldest detectors for nuclear radiation. The Geiger–Mueller counter is still used in nuclear applications for its reliability and low cost. The scintillation detector is one of the most widely used detectors. Popular scintillators are NaI(Tl), CsI(Tl)
or CsI(Na) and Bi₄Ge₃O₁₂ (commonly referred to as BGO). The solid state detector is used in applications when high-energy resolution is required.

Common neutron detectors are the boron counter, based on the (n,α) reaction ¹⁰B + n → ⁷Li + α + γ, the ³He detector, based on the (n,p) reaction n + ³He → ³H + p and special scintillators developed for neutron detection.

### 7 THE DETERMINATION OF WATER CONTENT IN SOIL AND BOREHOLES USING NEUTRONS

The principle of the determination of water content is the slowing down of fast neutrons. Fast neutrons emitted from a neutron source successively undergo the processes of slowing down, thermalization and diffusion. Hydrogen primarily determines the slowing down power of the medium, but it does not dominate its neutron transport property because of the presence of elements with very large neutron absorption cross-sections (e.g. Cl, Cd, In, Sm, Gd, B). These elements serve to keep the scattered neutrons in the vicinity of the source.

### 7.1 Definition of Porosity

It is common to express the water content in terms of porosity. The bulk density of an ideal formation consisting of uniformly distributed, fluid-filled pores in a rock matrix is \( \rho_B = \Phi \rho_f + (1 - \Phi) \rho_{ma} \). Here, \( \rho_f \) and \( \rho_{ma} \) are the fluid and rock matrix densities, respectively, and \( \Phi \) is the porosity. The porosity is given by Equation (15):

\[
\Phi = \frac{\rho_{ma} - \rho_B}{\rho_{ma} - \rho_f}
\]

When neutrons travel through matter from the point source, their fluxes decrease with distance. The rate of decrease is governed by a “scaling unit”, which is a property of the medium. The scaling units are the slowing-down length \( L_s \), which is a measure of the ability of the bulk medium to reduce the neutron energy to a final energy in a given distance, the diffusion length of thermal neutrons \( L_d \) (the distance that thermal neutrons travel until they are absorbed), and the migration length \( L_m \) of the neutrons from their original state as primary neutrons to the point of their absorption in the medium. These distance variables are related by the equation:

\[
L_m^2 = L_s^2 + L_d^2
\]

Experimental data show that the values of \( L_s \) and \( L_d \) depend mainly on the porosity of the rocks. This is because there is a certain degree of saturation of the pore space by water (or hydrocarbons when applied to well logging).

A neutron moisture gauge consists of a neutron source and one or two neutron detectors. The instruments are normally calibrated in terms of porosity or water content. The shape of the calibration curve relating detector count rate to porosity or water content is influenced by source–detector distance/geometry. There are two basic approaches to measuring the porosity: the short-spaced (source–detector) sonde used for soil moisture determinations and the long-spaced sonde used for borehole logging.

### 8 THE MONTE CARLO METHOD

The Monte Carlo method is a numerical procedure based on statistical theory. It is used to calculate the distribution of \( \gamma \)-rays or neutrons produced by one or more \( \gamma \)-ray or neutron sources in a medium of known chemical composition. Particle fluxes and response functions (reaction rates) in selected volume elements can be calculated with fair accuracies. The technique is useful in the design of nucleonic gauges to predict the optimum source–detector–shielding configuration. The gauge response for a particular configuration can be tested in a short time at low cost on PCs using Monte Carlo calculations. Thus, tedious, time-consuming and expensive laboratory measurements can be bypassed.

The concept of the Monte Carlo technique is tracking the transport through matter of neutrons or \( \gamma \)-rays by simulating the statistical nature of the interaction processes. This is based on the fact that the macroscopic cross-sections may be interpreted as a probability of interaction per unit distance traveled by the neutron or \( \gamma \)-ray. In Monte Carlo calculations, a set of neutrons/\( \gamma \)-rays histories is generated by following individual neutrons/\( \gamma \)-rays through successive collisions. The locations and results of collisions are determined from the range of possibilities by sets of random numbers. A large library of experimental nuclear data is used in the program to select the random numbers that influence the particle history. These include the direction of the first flight on leaving the source, the choice of interaction from those possible at each collision, the mean free path between collisions and the angle of emergence after collision. Tracking the particle finishes if the particle is either absorbed, passes a lower energy limit set by the user or crosses an outer boundary. Then the history of a new particle starts. In order to decrease the statistical errors of predictions obtained from Monte Carlo calculations, the tracking of many particle histories is needed. This is becoming more and more affordable, in both time and cost, with the advent of the new generation of powerful PCs. Codes for Monte Carlo calculations on PCs are readily available and
the technique has become a powerful tool in nucleonic gauge design and nuclear applications.

9 NUCLEAR TECHNIQUES FOR IN SITU ANALYSIS

Nuclear logging is well established and used routinely in the oil, gas, uranium and coal industries. It is essential for the oil and gas industries, in which very deep holes are drilled (thousands of meters). Owing to the deep penetration of $\gamma$-radiation and neutrons, nuclear logging can locate the presence of oil or gas behind the well casing.

The laboratory analysis of core samples retrieved from boreholes and nuclear logging are complementary. Although the core can provide all the information that can be extracted from a borehole, nuclear logging is able to provide information almost instantaneously. The volume of rock sampled by nuclear borehole logging is also much larger than the core samples and thus provides better sampling statistics, especially in heterogeneous deposits. There are a number of books published in this field: Hallenburg,\( ^9 \) Hearst and Nelson,\( ^{10} \) Tittman,\( ^{11} \) Ellis,\( ^{12} \) There are other books dealing with more specific aspects of nuclear logging. More recently, review papers have been published by Ellis et al.,\( ^{13} \) Mills et al.,\( ^{14} \) and Borsaru.\( ^{15} \)

Nuclear borehole logging techniques are either passive (natural $\gamma$) or active. In passive logging, the natural radiation in the borehole is measured by an appropriate detector, whereas in active logging an artificial radioactive source provides the radiation measured by the detector. Figure 4 shows a schematic diagram of a basic borehole logging system for nuclear logging. The borehole logging tool shown in the figure is fitted with one radiation detector. The source can be either a $\gamma$-ray source or a neutron source. In the absence of the source the tool is used for passive logging. Nuclear logging can be classified according to the radioactive source employed in the logging tool.

9.1 Passive Logging – Natural $\gamma$-Ray

The $\gamma$-ray spectral log technique provides a spectrometric measurement of the $\gamma$-radiation of rocks whereas the $\gamma$-log measures the intensity of the total natural $\gamma$-radiation.

![Figure 4](image-url) Schematic representation of a nuclear logging system.
of the rock. These techniques have widespread applications in petroleum and uranium exploration, potash, phosphate, coal, heavy minerals, iron ore and other mineralizations. In the γ-ray spectral log, the potassium, uranium and thorium components of the natural radiation are determined and the K, U, Th, U/K, Th/K and U/Th measurements are used for borehole lithology determinations and correlations. A review of γ-ray spectral logging has been written by Fertl.¹⁶

9.2 Active Logging

The backscattered γ-ray technique was developed for measuring the rock density, providing information on the type of rock encountered by the borehole, and in special cases for grade control. Figure 5 shows schematically a backscattered γ-ray spectrum obtained with a ⁶⁰Co γ-ray source. The backscattered spectrum is dependent on the intensity and energy of the primary γ-ray source employed in the logging tool and the type of rock intersected by the borehole. Czubek¹¹ reviewed the theory of γ–γ logging. The theory shows that the spectral intensity at high energy (>180 keV) is determined by the electron density, and at low energies by both the electron density and ²⁶⁵⁵₆⁵(eq see Equations 13 and 14). The count rate in the density region is related to the bulk density of the rock interrogated by the γ-radiation. The physical basis for the density measurement is that the Compton cross-section per electron is essentially independent of the atom in which the electron is bound, and in this energy region the only interaction of consequence is Compton scattering. The electron density is directly proportional to bulk density. The ratio of counts recorded in energy windows at high and low energies is proportional to ²⁶⁵⁵(eq. Since ²⁶⁵(eq is strongly dependent on the element of highest atomic number, e.g. Fe in iron ore, even a small variation of that element in a low-atomic-number matrix will cause significant variation in ²⁶⁵(eq. The ratio of counts recorded in energy windows at high energies (>500 keV) is proportional to the borehole diameter. In order to extract the most information from the backscattered γ-ray spectrum, the γ–γ logging must be spectrometric and automatic gain stabilization must be incorporated in the system.

Prompt γ neutron activation, neutron inelastic scattering and neutron activation are useful techniques in borehole logging. They require the use of a neutron source. The type of technique chosen depends on the particular application, the nuclei involved and the energy of the neutrons. When the neutron source is a neutron generator, both neutron inelastic scattering and prompt γ neutron activation can be performed simultaneously with the neutron generator operating in a pulsed mode. This technique is largely used in oil well logging.

9.3 Oil Well Logging

9.3.1 γ-Ray Source

The bulk density of rock formations is an important parameter in oil well logging. The new generation density-logging tool, the litho-density tool, measures both the formation’s bulk density and its photoelectric absorption, using a ¹³⁷Cs γ-ray source. This is carried out by recording the count rates in the Z-sensitive and density regions of the backscattered γ-ray spectrum shown in Figure 5. The photoelectric absorption ²⁶⁵(eq gives a measure of the average atomic number of the formation, which provides an indication of the lithology (sandstone, limestone, dolomite, etc.). The tool has two detectors at different spacings from the γ-ray source and has gain stabilization. Porosity can also be determined from the bulk density and ²⁶⁵(eq.
9.3.2 Neutron Generator

The neutron generator is well established in oil well logging. Owing to the high energy of the neutrons produced by the generator (14 MeV), the depth of investigation is greater than that for radioactive neutron sources. It can also excite many nuclear reactions that cannot be produced by steady-state sources. However, probably the most important feature of the neutron generator is that it can be pulsed, and this allows the development of special techniques that cannot be achieved with radioactive sources.

Neutron Die-away or Neutron Lifetime

This is an old technique developed for the determination of the chlorine content of formation fluid. A pulsed neutron source is needed and the neutron generator is an ideal one. The basis of this technique is to measure the change in neutron flux with time after a neutron burst. The fast neutrons emitted during the short neutron burst are slowed down to thermal energy and diffuse in the formation. They die when absorbed in a capture process by nuclei from the formation, and capture γ-rays are released. The number of capture γ-rays is proportional to the number of thermal neutrons present in the formation. The determination of neutron die-away is based on measuring the ratio of γ-ray count rates at two different times after the fast neutrons produced by the burst have decayed to thermal neutrons. The die-away log provides information to distinguish oil (low-capture cross-section with resulting slow γ-ray die-away rate) from saline water (high-capture cross-section and fast die-away rate) behind the steel casing in wells.

γ-ray Spectroscopy Using a Neutron Generator

Using a neutron generator in a pulsed mode makes it possible to separate the γ-rays released by neutron inelastic scattering from the γ-rays generated by the neutron capture process. Inelastic scattering γ-rays are emitted within a few nanoseconds of the fast neutron interaction and occurs during the neutron pulse. Capture γ-rays are produced after tens of microseconds by thermal neutrons traveling through the formation. Figure 6 shows schematically the gate timing of this tool. The tool is used to measure the carbon/oxygen and calcium/silicon ratios. By measuring both ratios, one can distinguish carbon in calcium carbonates from that in hydrocarbons and thus the presence of oil can be established. The energy of γ-rays released from neutron inelastic scattering with C, O, Ca and Si are 4.44, 6.1, 3.7 and 1.78 MeV respectively. A background spectrum is recorded in a time window of the same length, but with the generator turned off (see Figure 6). This is a capture spectrum and is subtracted from the inelastic spectrum. Schlumberger developed the Geochemical Logging Tool (GLT®). This tool makes the following spectral measurements: natural γ-rays produced by K, Th and U; Al by neutron activation with a 252Cf neutron source; and elements in the rock formation measured by capture γ-ray spectrometry using a pulsed neutron generator. The tool incorporates three scintillation detectors, a 252Cf neutron source and a neutron generator. Grau and Schweitzer developed a technique capable of measuring the absolute concentration of a number of elements present in the formation. The technique assumes that the composite spectrum measured in boreholes can be represented by a linear combination of known standard spectra. The weighted least-squares method of fitting the entire spectrum with the set of standard spectra extracts the chemical composition. The measured spectrum is decomposed into elemental standards. Carbon and oxygen are not measured by the GLT® but are accounted for by the chemical combination of each element measured in the capture spectrum as a single oxide or carbonate. The tool is used to derive mineralogy and petrophysical parameters from the elemental concentrations.

9.3.3 Steady-state Neutron Sources

Am–Be is used for porosity measurements. Single-detector tools employing mostly epithermal neutron detection or two-detector neutron sondes employing thermal neutron detection are commonly used in oil well logging for porosity measurements.
9.3.4 Natural γ-Ray Spectral Logging

Natural γ-ray spectral logging provides information about the presence of clays in the formation matrix. The tendency is to replace the natural γ-ray tools recording the count rates in the three K/U/Th windows with fully spectrometric tools, which record the whole spectrum in 256 channels.

9.3.5 Measurements While Drilling

Measurements while drilling are used to gather information on the formation being drilled in real time. The detectors are mounted in the drilling string near the bit. The detectors are either scintillators or Geiger–Mueller tubes that have been ruggedized to withstand the drilling process. γ-Ray, neutron porosity and density measurement-while-drilling (MWD) tools have been developed and are widely used.

9.4 Uranium

9.4.1 Natural γ-Ray Logging

γ-Rays emitted from the uranium minerals are routinely used for both quantitative and qualitative determination of uranium in exploration or ore-body evaluation. The γ-rays are ideal to use as intrinsic indicators for uranium as they occur naturally, sample relatively large volumes of material and are simple to detect and identify. The decay series of $^{238}\text{U}$ (excluding some short-lived isotopes) is:

$$
\begin{align*}
^{238}\text{U} & \rightarrow ^{234}\text{U} & (4.5 \times 10^5a) & \rightarrow ^{234}\text{Th} & (2.5 \times 10^5a) & \rightarrow ^{230}\text{Pa} & (8 \times 10^4a) & \rightarrow ^{226}\text{Ra} \\
& \rightarrow ^{222}\text{Rn} & (1620a) & \rightarrow ^{214}\text{Pb} & (3.8d) & \rightarrow ^{210}\text{Pb} & (27\text{min}) & \rightarrow ^{206}\text{Pb}\text{(stable)}
\end{align*}
$$

When secular equilibrium is reached after some 10$^6$ years, the activity of each isotope, except $^{206}\text{Pb}$, in the decay series is equal. Disequilibrium can occur throughout the chain if one or more of the daughter products is lost by any process other than radioactive decay. Since each daughter product is an element with its own characteristic physical and chemical properties, it may behave differently within a given environment. For example, $^{222}\text{Rn}$ is a gas. Also, the solubilities of radium, uranium and thorium differ, and preferential leaching of elements may occur.

Total γ-ray Logging This is probably the easiest logging technique for quantitative analysis. The total number of γ-rays can be recorded with either a Geiger counter or a scintillator. The logging probes are calibrated in special uranium test pits. Since this method records γ-rays from many daughters of uranium, it can only be applied for quantitative analysis if both the test pit and uranium ore body are in secular equilibrium.

Accurate Spectral γ-ray Logging The principle of this technique for the in situ quantitative determination of uranium is measurement of the γ-radiation (1001 keV) produced during the decay of protactinium-234 ($^{234}\text{Pa}$) to uranium-234. In the uranium decay series, $^{238}\text{U}$ first decays to $^{234}\text{Th}$, which decays to $^{234}\text{Pa}$, which in turn decays to $^{234}\text{U}$. Because the half-lives of all three reactions are short, it is unlikely that in nature the $^{238}\text{U}$ and $^{234}\text{Pa}$ will become separated. Thus, the determination of the $^{234}\text{U}$ grade from the count rate of the 1001 keV γ-ray gives a measure of the $^{238}\text{U}$ grade in the ore body. This method is independent of the amount of disequilibrium in the ore body. A high resolution (intrinsic Ge detector) is necessary to measure the count rate of the 1001 keV, which is weak in comparison with other γ-ray lines in the natural γ-spectrum.

9.4.2 Delayed Fission Neutrons

Fission occurs when uranium nuclei interact with neutrons and the nuclei split into fission products, emitting neutrons. Two to three percent of the fission products are unstable and β-decay, forming other nuclei. By doing this, each fission product emits one neutron. These are called delayed neutrons and are emitted with different half-lives, between 0.2 and 50 s. This is the basis of the delayed fission neutron technique for quantitative analysis of uranium and is independent of the state of equilibrium of the uranium ore body. The technique consists of irradiating the uranium ore with neutrons, removing the neutron source and counting the delayed neutrons after the source neutrons disappear.

The neutron generator is well suited for this application. The generator is pulsed and then turned off. When the neutrons produced by the generator die away, the delayed neutrons are counted. The effect of diffusion of the neutrons in the medium must be accounted for. Background subtraction is achieved using the reaction $^{17}\text{O}(n,p)^{17}\text{N} \rightarrow ^{16}\text{O} + n$.

$^{252}\text{Cf}$ is also used as a source of neutrons by shuttling the source inside the moving probe between two detectors; while one detector is counting the delayed neutrons, the source is irradiating the ore body. Owing to the much lower energy of the neutrons produced by $^{252}\text{Cf}$, no background subtraction is needed (the energy of the neutrons is below the threshold energy of the $^{17}\text{O}(n,p)$ reaction). Correction for diffusion of the neutrons in the uranium ore is needed.

9.4.3 Prompt Fission Neutrons

The neutrons emitted immediately after fission can also be used to measure the uranium concentration. The
technique uses a neutron generator as the primary source of neutrons. An epithermal neutron detector is gated off during a neutron pulse and starts counting epithermal neutrons immediately after the pulse, while thermal neutrons are present and causing fission. The uranium concentration is determined from the ratio of epithermal neutrons to (i) thermal neutrons or (ii) thermal neutron die-away time.

9.5 Coal

Nuclear borehole logging is used routinely in the exploration for coal and its acceptance in the mining stage for coal quality control is increasing. The parameters determining the economic value of coal are the thickness and depth of the coal seams and the quality of coal. Coal quality is determined by the “raw ash” content, calorific value, rank, moisture content, volatiles and the elemental composition of the ash. These parameters are determined from the coal core in the laboratory. However, this complete information is not always needed. In many cases it is sufficient to measure only thickness, depth and the raw ash content of the coal seams, and this can be achieved by nuclear logging in “easier to drill open holes”. Natural-γ, γ–γ and prompt neutron–γ techniques are all used for coal logging. Natural-γ is used to delineate the coal seams based on the fact that coal is low in natural radiation compared with the interseam sediments.

The γ–γ Technique

This technique was developed for the coal mining industry in the 1970s. It is used mostly for the delineation of coal seams based on the difference in density between coal and sediments. The ash content of the coal seams can be derived indirectly from the correlation between ash and density. Good density–ash correlations are found for many coal deposits. However, this correlation is not universal. A direct measurement of ash in coal is achieved using the spectrometric γ–γ technique. This technique relies on the fact that variations in the ash content of coal correspond to changes in $Z_{eq}$. When the ash content and $Z_{eq}$ are uniquely correlated, ash content can be measured by counting changes in $Z_{eq}$. This is carried out by calculating the $P_z$ ratio between count rates recorded in two broad spectral windows at high and low energies in the backscattered γ-ray spectrum. This measurement requires gain stabilization.

The Prompt Neutron–γ Method for Determination of Ash in Coal

Owing to its high hydrogen content, coal is an excellent medium for the neutron capture technique. The neutrons emitted by the neutron source are thermalized by colliding with the hydrogen nuclei present in coal and subsequently interact with the nuclei in the coal matrix. The basis for ash determination is the correlation that exists between ash and the main constituents of ash, i.e. Al, Si and Fe or a combination of two of these elements. Charbucinski et al. developed a method based on the neutron–γ technique for the determination of ash content, depth and thickness of coal strata. The technique was later extended for the measurement of Fe in coal.

Coal Face Ash Analyzer

Coal ash determination at the coal face falls into the category of in situ determination. A portable instrument capable of monitoring the quality of exposed coal seams and differentiating between coal seams and “look-alike” coal sediments is useful for the coalmining industry. Wesolinski and de Jesus developed a technique for the determination of ash on the coal face based on the simultaneous measurement of the backscattered γ-radiation at two different energies. They developed a portable instrument that can locate the coal–seam interface and measure the ash content on the coal face. The activity of the γ-ray sources employed in the instrument was 185 MBq. Borsaru et al. developed a coal face analyzer based on the measurement of natural γ-rays. The technique relies on the correlation between the natural γ-radiation of the coal and its ash content. Another coal face analyzer based on the backscattered γ–γ technique was developed more recently by Borsaru et al. It uses two microsources ($^{133}$Ba and $^{137}$Cs) of total activity 2.2 MBq. By employing such low-activity γ-ray sources, the analyzer does not need special shielding and the user is not exposed to unacceptable levels of radiation.

9.6 Iron Ore

The backscattered γ–γ technique has been employed for the simultaneous measurement of iron grade, density and borehole diameter in wide (310 and 380 mm) dry blast holes in iron ore deposits. The primary γ-ray source was 165 MBq $^{60}$Co. The backscattered γ-ray spectrum was stabilized using a $^{60}$Co microsource. The borehole diameter was measured using the ratio (S-factor) between count rates in energy windows at intermediate energies (400–700 keV) and at high energies (700–950 keV). The source-to-detector separation was 70 cm. The iron grade determination was based on the $P_z$ technique described earlier. The accuracy for ore grade obtained in 1.5 m splits was 1.9% Fe in ore in the range from 35% to 69% Fe and 3% Fe for ores in the range of iron content 9–69% Fe.

ABBREVIATIONS AND ACRONYMS

MWD Measurement-while-drilling
where $R$ approximately equal to the radius of the nucleus with mass $A$. When a neutron interacts elastically with a nucleus, the relation between the neutron energy before and after scattering, $E_1$ and $E_2$ respectively, is illustrated in Equation (20) as:

$$\frac{E_2}{E_1} = \frac{A^2 + 2A \cos \theta + 1}{(A + 1)^2} \quad (20)$$

where $A$ is the mass of the target nucleus and $\theta$ is the scattering angle in the center-of-mass system. Equation (20) reveals four features of elastic scattering: the fractional energy loss depends only on the mass ratio and scattering angle and is independent of energy. The minimum possible value $E_{2\text{min}}$ of $E_2$ (corresponding to $\theta = 180^\circ$) is $E_{2\text{min}} = [(A - 1)/(A + 1)]^2$ and is the result of a head-on collision. For $\theta = 0$, a glancing collision, $E_2 = E_1$, and no energy loss occurs. When $A = 1$, corresponding to collision with a hydrogen nucleus, for $\theta = 180^\circ$ (head-on collision), $E_2 = 0$ and all the neutron’s kinetic energy is transferred to the recoiling proton.

The percentage decrease in the neutron energy as the result of a collision, expressed as the average logarithmic energy decrement $\xi$, is known as neutron lethargy and is defined in Equation (21) as:

$$\xi = \ln \left( \frac{E_1}{E_2} \right) = \frac{E_{2\text{min}}}{E_1} \left( \ln \left( \frac{E_1}{E_2} \right) \right) P(E_2) \, dE_2$$

where $P(E_2)$ is the probability that the scattered neutron will have energy $E_2$. When the integrations are performed, it is found that the mean lethargy increase per collision, $\xi$, illustrated in Equation (22) is:

$$\xi = 1 + \frac{(A - 1)^2}{2A} \ln \frac{A - 1}{A + 1} \quad (22)$$

Radiochemical Methods: Introduction

Rolf J. Rosenberg
VTT Chemical Technology, Espoo, Finland

1 INTRODUCTION

Roentgen announced the discovery of X-rays in 1895. This led to extensive use and study of this phenomena, which had already been studied since 1859 without the realization of its true nature. By 1897, a number of injuries caused by X-rays had already been reported from laboratories all over the world. In the same year Bequerel discovered radioactivity and soon after, in 1900, the first skin burn caused by radioactivity concentrated from uranium ore, was produced. The Curies learned to produce radium, which found use in luminous paints in instruments and clocks during and after World War I. The health effects of radium were unknown to the public and workers involved in painting licked the brushes to point them. This digestion of radium, and the use of radium for medical purposes, led to many deaths from bone cancer and aplastic anemia. As late as 1944–1951 a radium compound was used as a cure for tuberculosis in Germany. It has been estimated that more than 100 persons died from the effects of radium. Another cause of a number of deaths from cancer caused by radioactivity is radon and its daughters. In Eastern Europe many mines for heavy metals also contain uranium. Radon and its daughters that are incorporated into uranium caused a fatal lung disease, which was later identified as cancer. Information about this did not reach miners in the USA. Therefore the intense uranium mining that took place in the USA, starting after World War II, also caused numerous fatalities from lung cancer.

These cases have been studied thoroughly leading to an understanding of the effects of radiation and how to avoid it. Thus, early experiences with the use of nuclear reactors and in building atomic bombs during World War II could be managed with a good safety record. The health effects of the atomic bombs in Hiroshima and Nagasaki have also been thoroughly investigated, yielding a great deal of information. As a consequence the health effects of ionizing radiation are well known. Based on this knowledge, international safety regulations have been set on allowed doses, allowed radionuclide concentrations in water, food and air and so on. It can safely be said that the regulations are such that human beings are much better protected against radioactivity than against chemical toxicity.

After World War II the cold war resulted in the nuclear weapons race. Both the USA and the Soviet Union conducted nuclear weapons tests above ground. The fallout of fission and activation products from these tests spread over the northern hemisphere. This started research in all countries, in which the environmental pollution and transport of these radionuclides were studied. Much work was done in the development of analytical methods for the determination of radionuclides. The nuclear industry, nuclear power plants and reprocessing plants during their normal operation caused some additional release of radionuclides. Major releases were caused by accidents in the Soviet Union, USA and UK. New threats have appeared with the disintegration of the Soviet Union. Lack of funds has increased the risks of accidental releases from nuclear submarines, reprocessing plants and nuclear power plants.

All these are good reasons for continuous monitoring of radionuclides in the environment. New reasons for measurement of low activities and long-lived radionuclides have developed in connection with research on the disposal of spent fuel and reprocessing waste. As a consequence, new methods of making these measurements are continuously being developed. In addition to the classical radiometric methods, new mass spectrometric methods are published.

2 PROPERTIES OF RADIONUCLIDES

2.1 Nuclides and Radioactive Decay

An element is identified by the number of positively charged protons in its nucleus and the consequent number of negatively charged electrons. In addition to protons,
the nucleus contains neutrons, which do not carry any charge. Neutrons and protons have an atomic weight of unity. The mass of electrons is negligible compared with the mass of protons or neutrons. All elements consist of isotopes. Each isotope of an element is identified by the number of neutrons. Thus all isotopes of a specific element contain the same number of protons, which is determined by the atomic number, Z. The mass (M) of the isotope is the sum of the number of protons and neutrons in the nucleus. A specific combination of protons and neutrons is called a nuclide. A nuclide is identified by its Z and M values. The chemical symbol gives the Z and the mass is given as a superscript on the left side of the chemical symbol. $^{238}$U is uranium with mass 238; it is called uranium-238. $^3$H is called hydrogen-3, or tritium. Most elements, but not all of them, have several stable isotopes, in a ratio that is constant. Thus nuclides with the same Z are called isotopes, nuclides with the same mass are called isobars and nuclides with the same number of neutrons are called isotones.

In addition to the stable isotopes, all elements have radioactive isotopes with variable half-lives. A radionuclide is unstable, which means that the nucleus decays releasing energy and particles. This is seen as emission of radiation of various kinds. Part of the energy is released in the form of electromagnetic radiation, like $\gamma$-rays, and partly as kinetic energy of emitted particles. This energetic ionizing radiation is what makes radionuclides hazardous for living organisms. The rate of decay is characteristic for each radionuclide. If there are N atoms the rate is $-dN/dt$, which is proportional to N according to Equation (1)

$$\frac{dN}{dt} = -\lambda N \quad (1)$$

Instead of the disintegration constant $\lambda$, the half-life $T$ is commonly used. The relation is, Equation (2)

$$\lambda T = \ln 2 = 0.693 \quad (2)$$

The half-lives of the different radionuclides vary between fractions of seconds to billions of years. The energy released is expressed in units of electron volts, eV. This is the energy required to transport an electron through a potential difference of 1 V. Because nuclear binding energies are of the order of 8 MeV per nucleon, nuclear reactions always release significant amounts of energy. Therefore the kinetic energies of the emitted particles usually vary from a few kiloelectron volts to several megaelectron volts.

The amount of an element is usually expressed as a weight unit like kilogram or gram, or a concentration unit like grams per kilogram, grams per liter or such. Lately the more scientific unit, the mole, is used, in order to relate the quantity to the number of atoms or molecules. The amount of stable nuclide is usually expressed as isotopic percentage, that is the ratio of the total number of atoms of the element. The amounts of very long-lived radionuclides are also expressed in this way, for instance $^{238}$U and $^{235}$U. Of course the amount of both stable nuclides and radionuclides may be expressed in absolute mass units or as the number of nuclides. Particularly when the amount of a long-lived radionuclide has been determined by mass spectrometry, it is not uncommon to give the results in mass concentration units.

The mass of a radionuclide with a short half-life is very small compared with its activity. The activity also has the benefit of being proportional to its toxicity, which is the usual reason for determining the concentration. The methods most commonly used for the determination of the radionuclide are radiometric, which give the activities directly. For these reasons the amounts of radionuclides are usually expressed in units of radioactivity. The activity of a radionuclide is expressed as disintegrations per unit of time. The basic unit is the Bequerel, Bq. This is the number of disintegrations per second. Greater and smaller units are kBq, MBq, GBq and mBq.

An older unit of activity, seen in older texts and still in use in the USA, is the curie (Ci). One Ci is $3.7 \times 10^{10}$ Bq. Because the unit is quite large it is common to use smaller units like mCi, $\mu$Ci, nCi and pCi especially in expressing environmental activities.

### 2.2 Decay Modes

Radionuclides decay in different ways. Isomeric transitions (IT), that is transitions between different energy levels of the same nuclide, result in emission of energy only, normally in the form of a $\gamma$-ray, $^{60}$Co $\rightarrow$ $^{60}$Co + $\gamma$. This usually occurs in connection with emission of particles, but separate IT with measurable half-lives are also known. When the transition energy is greater than 1.022 MeV, pair production may occur. This means that an electron positron (positively charged electron) pair is emitted instead of the $\gamma$-ray. There is also a third mode of IT: internal conversion in which an electron from the electron cloud carries the de-excitation energy and a conversion electron is emitted.

$\beta$-Decay is the most common form of decay of a radionuclide. Most radionuclides formed by fission or by neutron activation reactions are neutron rich, and they decay mainly by emitting a negatively charged $\beta$-particle, that is a $\beta^-$-particle or radiation. In most cases, but not always, the daughter nuclide is left in an isomeric state which decays either immediately or with a measurable half-life by emitting one or several $\gamma$-rays.

Proton-rich nuclides, usually produced by $\gamma$-ray or charged particle reactions, disintegrate by positron- ($\beta^+$)
emission or by electron capture. In electron capture the charge of the nucleus is adjusted by capturing a negative electron instead of emitting a positive $\beta$-particle. In this case the only measurable radiation is the X-ray which is emitted when the captured electron is replaced by another from a higher energy level.

Heavy nuclides, $Z > 82$ with a few exceptions, may decay by emission of an $\alpha$-particle, which is a $^4$He nucleus. The $\alpha$-particles usually carry much energy.

The most heavy elements, $Z > 90$, may undergo spontaneous fission in which the nucleus is divided into two fractions of comparable, but not equal, size. Two to three neutrons are also emitted, and often also $\gamma$-radiation.

### 3 MEDICAL USE OF RADIONUCLIDES

As has been indicated above radionuclides were used for their believed health effects early in the period following the discovery of radionuclides. One of the most important applications is the use of radiation for cancer treatment. In the beginning large $^{60}$Co sources were used to treat cancer. These pose a potential environmental hazard because the $^{60}$Co sources have to be disposed of in some way. $^{60}$Co sources have largely been replaced by linear accelerators. The radiation doses have to be measured and controlled with high accuracy.

Different short-lived radionuclides, inserted into humans in a number of ways, are used for both treatment and diagnostics. The radionuclides are usually used as labeled compounds. The substrate on to or into which they are adhered are chosen so that they transport the radionuclides into specific organs of the human body. They can then be determined by measuring the gamma radiation which they emit. Gamma cameras enable the measurement of the radionuclide distribution in two or three dimensions. These measurements reveal tumors and other kinds of deficiencies in the human body. The radioisotopes used in medical applications are usually so short-lived that they do not pose any environmental hazards.

Radionuclides are also used as labels in radioimmunoassay, which is used for the determination of biologically active compounds.

### 4 INDUSTRIAL USE OF RADIONUCLIDES

The production of nuclear weapons and the use of nuclear energy have been the largest industrial-scale activities involving radionuclides. The first nuclear weapons were based on enriched uranium, but soon plutonium was used instead. The plutonium is produced by irradiating uranium in research reactors. The plutonium has to be chemically separated from the uranium and large amounts of radionuclides are produced by fission of uranium during the irradiation. The use of nuclear energy involves radioactivity during uranium mining and reprocessing of the fuel. These activities cause large amounts of radioactive waste, which have to be stored in a safe way. This has not always been successful, as will be indicated below. Uranium and plutonium and their isotopes have to be measured during the different stages of the processes.

Other industrial uses involve radioactive sources in a number of gauges. Radiography using $^{60}$Co and $^{137}$Cs sources is in use. In industrial plants such parameters as thickness and density are commonly measured in the process using gauges based on radioactive sources. These usually do require calibration measurements and after dismantling they need to be disposed of in a safe way.

### 5 USE OF RADIONUCLIDES IN RESEARCH

Radionuclides are produced in research reactors and accelerators for use in medicine, as tracers and in analytical chemistry. The medical uses have already been mentioned. Radioactive tracers are used as labels in biochemical and chemical research in order to study chemical reactions. Radioactive tracers are also used to study industrial processes, transport of water and air and wear of engines, to mention some applications.

Nuclear reactions and activation analysis are used for materials research and trace element analysis of environmental, geological, archaeological, biological and industrial materials.

### 6 ORIGIN OF RADIONUCLIDES IN THE ENVIRONMENT

Radionuclides occur naturally in the environment. They can be found in the atmosphere, in all natural waters, in rocks, and so on. Usually the amounts are small, but sometimes quite large activities can be found. All living systems contain radionuclides. Most of them are of natural origin, but after World War II an increasing amount of radioactivity has been distributed in the environment by human activity.

Uranium and thorium are elements which exist in amounts in the microgram per gram range in rocks, particularly granitic rocks. Both are radioactive consisting mainly of the isotopes $^{235}$U with a half-life of $7.13 \times 10^8$ years, $^{238}$U with a half-life of $4.468 \times 10^9$ years and $^{232}$Th with a half-life of $1.405 \times 10^{10}$ years, sufficiently
long half-lives to enable the isotopes to have survived the billions of years in which the earth has existed. These long-lived radionuclides support a long line of daughter nuclides with variable half-lives, the uranium–actinium, uranium–radium and thorium series. These series have the gas radon, Rn, as an intermediate isotope. As an inert gas, radon emanates and is thus spread into houses and the atmosphere in areas of high uranium content in the bedrock. For instance in Finland, 75% of the radiation dose to the population from natural sources is caused by $^{222}$Rn and its daughters. Because of the volatility of radon, its daughters $^{210}$Pb and $^{210}$Po may be found in the atmosphere. A part of the $^{210}$Po is directly volatilized when coal is burned in power plants. Some coals contain significant amounts of uranium and its daughters. These three natural series all end of in stable nuclides of lead. Thus $^{206}$Pb, $^{207}$Pb and $^{208}$Pb are at least partly of radioegenic origin, and therefore the lead isotope ratios are not constant, which is opposite to the case for most other isotope ratios. As uranium and thorium are natural constituents of rocks, they can also be found in all materials containing stone, such as the concrete walls in houses.

Another original radionuclide in the bedrock is $^{40}$K, with a half-life of $1.26 \times 10^4$ years. $^{40}$K is mixed with all the potassium of the earth in a constant ratio. Therefore all rocks, building materials, waters and living systems also have their share of $^{40}$K.

New radionuclides are constantly produced in small amounts by cosmic ray-induced nuclear reactions in the atmosphere. More than ten different nuclides are produced. The most significant ones in respect of quantity are $^3$H, $^{10}$Be, $^{14}$C, $^{26}$Al, $^{26}$Cl and $^{39}$Ar.

Radionuclides have significant uses in medicine, industrial processes, industrial measurement systems and science. Thus radionuclides are produced artificially by different kinds of accelerators and nuclear reactors. However, most of these radionuclides have short half-lives and the contamination of the environment from these sources is insignificant. Artificial nuclides that have been incorporated into the environment mainly originate from nuclear weapons tests and the nuclear energy fuel cycle. In nuclear weapons tests and nuclear power production the main process is fission of $^{235}$U (reactors) or $^{239}$Pu (bombs). In both instances radionuclides are produced via two kinds of nuclear reaction. The main process is the fission itself, but significant amounts of radionuclides are also produced by activation via neutrons which are released in the fission process. During fission, all radionuclides in the mass range 80–110 and 125–155 are produced. The most significant ones in regard to safety are $^{131}$I with a half-life of 8 days, $^{90}$Sr with a half-life of 28.5 years and $^{137}$Cs with a half-life of 30.2 years. The neutron activation reaction produces some rather short-lived nuclides like $^{54}$Mn (312 days) and $^{60}$Co (5.3 years), but the most significant with respect to safety are the long-lived actinides, such as $^{239}$Pu (24 110 years). The nuclear weapons tests performed in the atmosphere during the 1960s severely contaminated the globe with these radionuclides. In 1986 the Chernobyl accident contaminated large areas of Europe with significant amounts of radioactivity. Starting from World War II, local contamination has occurred in several locations dealing with nuclear weapons production and reprocessing of nuclear fuel especially in the USA, UK and Russia. Although local, the radionuclide contamination from Windscale (Sellafield), UK, can be seen in the ocean up to the North Pole. Compared to these releases, releases from nuclear power plants are insignificant. Research connected with the final disposal of spent nuclear fuel has increased interest in the behavior of other long-lived nuclides produced in nuclear fuel. In addition to $^{238}$Pu, nuclides like $^{90}$Tc, $^{129}$I and $^{237}$Np have been increasingly studied.

In Europe the disintegration of the Soviet Union has introduced new needs for radionuclide measurements through threats from the disintegration of nuclear submarines in the Barents Sea and the poor maintenance of nuclear power plants.

7 MEASUREMENT OF RADIONUCLIDES

Originally radionuclides were always measured by radiometric methods, that is by measuring the radiation emitted at the decay. This is convenient for several reasons. In most cases it is the simplest way of doing the measurement. The sensitivity is excellent, the instrumentation usually of low cost, and instrumental detection is often possible. Short-lived radionuclides have a high activity, whereas the mass of the nuclide is usually very low. The signal per unit weight material obtained is very high for short-lived nuclides. This can be illustrated by the following examples. One Bq corresponds to 0.3 pg of $^{137}$Cs (half-life 30 years), 27 pg of $^{226}$Ra (half-life 1599 years) and 152 ng of $^{129}$I (half-life 1.57 × 10$^7$ years). Therefore nonradiometric methods have not been considered for the determination of important radionuclides like $^{90}$Sr, $^{137}$Cs, $^{241}$Am and the different Cm isotopes. Radiometric methods also give the measure of the property sought directly, that is the radiological toxicity. Therefore radiometric methods are dealt with first and more thoroughly. A number of compilations and conference proceedings describe methods to determine radionuclides.

In this encyclopedia, radiometric methods and their applications are described in the following articles:

Nuclear Detection Methods and Instrumentation
$\gamma$-Spectrometry, High-resolution, for Radionuclide Determination
However, nuclear weapons testing and the nuclear industry, especially nuclear waste research, have introduced the need for measurement of long-lived radionuclides. In assessing the long-term environmental effects of nuclear power production, the disposal of radioactive waste in general and spent fuel in particular, a number of long-lived radionuclides have to be considered. These are $^{99}\text{Tc}$, $^{129}\text{I}$, $^{237}\text{Np}$ and $^{239}\text{Pu}$.

For very long-lived nuclides the specific activity may be so low that detection limits are too poor for certain types of sample. When the mass (or number of atoms per unit weight) becomes significant compared to the intensity of the emitted radiation per unit weight of the radionuclide, other mass-sensitive detection methods may be more favorable. An example of this is given by Toole et al.(17) While the $\alpha$-spectrometric detection limit is 0.1 mBq for all actinides, the detection limit for inductively coupled plasma mass spectrometry changes from 0.004 μBq to 84 mBq when the half-life of the nuclide changes from $1.4 \times 10^{10}$ to $6.5 \times 10^3$ years ($^{232}\text{Th}$ and $^{240}\text{Pu}$ respectively).

McMahon(18,19) and Rosenberg(20) have discussed all kinds of mass analytical techniques feasible for the determination of long-lived radionuclides. However, in normal cases the radionuclide has to be determined in a mixture with its stable isotopes with a very unfavorable mass ratio, or in a mixture with its radioactive isotopes. This means that methods capable of isotope analysis are needed. The only exception is $^{99}\text{Tc}$, because it is the only isotope of Tc found in nuclear fuel. There are several references to the use of a number of analytical techniques for the determination of $^{99}\text{Tc}$ compiled by Long and Sparks.(21)

In practice the methods used are neutron activation analysis and mass spectrometry. These methods are described in this encyclopedia in the following articles:

**Neutron Activation Analysis in the Determination of Very Long-lived Radionuclides**

**Mass Spectrometry of Long-lived Radionuclides**

**Actinides and other Alpha-emitters, Determination of**

In order to understand the behavior of radionuclides in the environment, it is not always sufficient to know their concentrations in different samples. There is also a need to know their physicochemical forms, their species. Therefore we have included one article describing methods for speciation of radionuclides:

**Speciation of Radionuclides in the Environment**

To assay an actinide or other α-emitter at the low concentrations encountered in many environmental samples necessitates chemical separation of the actinide of interest from the bulk matrix, purification by the elimination of other interferants, mounting onto a suitable substrate for counting, and quantification by radiometric, mass spectrometric or other means. In this contribution, the chain of analysis from sampling to counting is critically reviewed and many of the most important pitfalls and sources of error are highlighted. Specifically, the pretreatment, preconcentration, separation and purification steps required for the assay of thorium, uranium, neptunium, plutonium, americium and curium in a wide range of environmental matrices are examined in detail. Emphasis is given to the need for appropriate radiochemical yield monitors and to the practical application of ion exchange, solvent extraction and extraction chromatography in the purification of these elements. This is complemented by a description of methods for the preparation of quality sources suitable for counting by α-spectrometry, liquid scintillation α-spectrometry and mass spectrometry. In addition, an overview is given of the operational principles and systems used in α-radiometry and mass spectrometry, including a discussion of the practical limits of detection and quantitation achievable with these systems. Finally, the importance of traceability and good quality assurance in precision actinide assay is emphasized.

1 INTRODUCTION

The actinide series of the periodic table comprises the naturally occurring thorium, protactinium and uranium nuclides, and the transuranium elements neptunium to lawrencium, inclusive. Small traces of naturally produced transuranium nuclides remain or are being generated in nature (1–3) but the overwhelming “weight” of present environmental inventories of these elements derive from human activities, related mainly to the nuclear fuel cycle.
and to military applications. Although direct quantitative measurement of some of these nuclides is possible by non-destructive techniques such as \( \gamma \)- and X-ray spectrometry, most of them decay by the emission of \( \alpha \)- or \( \beta \)-particles, or by processes such as electron capture and isomeric transitions without accompanying \( \gamma \)-emissions. For these nuclides, direct measurement in the presence of the host matrix is not possible, as the particles emitted are rapidly absorbed by the matrix before they can be detected. At environmental level, even those nuclides with \( \gamma \)- and X-ray emissions may be difficult to detect, given the minute concentrations involved, the comparatively low sensitivity of \( \gamma \)- and X-ray detection systems, and interference from other photon-emitters in the sample. In such cases, radiochemical separation of the nuclides of interest from the bulk matrix, purification by the elimination of other interfering agents and preparation in a form suitable for counting are essential. Accurate determination of actinide concentrations at these low levels depends heavily on the analyst’s ability to prepare extremely pure analytes, free of any gravimetric or radiometric interferences which could lead to complications in the interpretation of the measured spectra.

Since most of the actinides spontaneously decay by \( \alpha \)-emission, high-resolution \( \alpha \)-spectrometry has become the most widely used technique for the determination of these nuclides. However, a number of alternative techniques, such as inductively coupled plasma mass spectrometry (ICPMS) and accelerator mass spectrometry (AMS), are becoming increasingly popular.

Over the years, numerous radiochemical separation schemes, based primarily on coprecipitation, ion exchange or solvent extraction, have been proposed and adapted for different matrices and types of analysis. In this contribution, an up-to-date review of many of these separation schemes is presented, together with a detailed description of those schemes most widely used today. Although the techniques described are valid in general and can be applied to the analysis of a wide range of concentration levels, our discussion here will focus on the analysis of \( \alpha \)-emitting radionuclides present at trace or indicator level in environmental matrices. Specifically, attention will be paid to the determination of environmental concentrations of the naturally occurring thorium and uranium \( \alpha \)-emitting nuclides, and the transuranium nuclides neptunium, plutonium, americium and curium.

2 YIELD MONITORS: NECESSITY AND CHOICE

Since the separation of the nuclides of interest from a host matrix involves physical and chemical operations which are unlikely to be quantitative or reproducible from one sample to another, precise determination of a particular actinide’s concentration in an environmental sample requires the use of a chemical yield monitor with which to assess the overall recovery of the operations involved. Because the actinides have no stable isotopes, other radioactive isotopes of these elements are employed by most laboratories as chemical yield monitors.

The basic requirements and some of the difficulties encountered when using chemical yield monitors in actinide analyses at environmental concentrations have been discussed in detail by several authors.\(^{4-6}\) Essentially, a suitable yield monitor should have the same chemical behavior as that of the determinand at all stages of the analysis, should be in complete physical and chemical equilibrium with the determinand from the earliest possible stage of the process, and should not interfere with its measurement. Further limitations are imposed by half-life, production costs, purity of the yield monitor and, most importantly, the presence of the intended tracer in the environmental materials to be analysed. The choice of yield monitor and the suitability and availability problems encountered are best illustrated by considering each element separately.

2.1 Monitors for the Analysis of Thorium

Of the thorium isotopes, \( \alpha \)-emitting \(^{228}\text{Th}\) \((t_{1/2} = 1.91\text{ years})\), \(^{230}\text{Th}\) \((t_{1/2} = 7.7 \times 10^4\text{ years})\) and \(^{232}\text{Th}\) \((t_{1/2} = 1.41 \times 10^{10}\text{ years})\) are widely used as geochronometers and as powerful tracers of oceanographic processes. In sediment dating, \(^{228}\text{Th}\) is frequently used as a yield monitor for \(^{230}\text{Th}\) and \(^{232}\text{Th}\). Its use, however, is predicated on the absence of \(^{238}\text{U}\) from the sample in question. When, as is often the case, significant amounts of \(^{228}\text{Th}\) are present in the sample, or when this nuclide is the object of the analysis, an alternative yield monitor must be employed. This is usually \(^{234}\text{Th}\) \((t_{1/2} = 24.1\text{ days})\), which has traditionally been employed as an isotopic yield monitor for the radiochemical determination of \(^{228}\text{Th}\), \(^{230}\text{Th}\) and \(^{232}\text{Th}\). Although \(^{234}\text{Th}\) can be prepared easily from a \(^{238}\text{U}\) solution with good isotopic purity, the main difficulties associated with the use of this nuclide are its relatively short half-life, its occurrence in the sample, and the fact that it decays by both \( \beta \)- and \( \gamma \)-emission, thus requiring a separate radiometric determination.

Another alternative is \(^{229}\text{Th}\), which is being employed increasingly.\(^7\) The main advantages of this nuclide as a monitor are its long half-life \((t_{1/2} = 7340\text{ years})\) and its decay by \( \alpha \)-emission, which simplifies counting, requiring a single radiometric determination. The complexity (i.e. multicomponent nature) and energy spread of its \( \alpha \)-“peak”, and its close proximity to the \(^{230}\text{Th} \) “peak” (actually an unresolved doublet) require the preparation
2.2 Monitors for the Analysis of Uranium

Uranium analysis is usually based on the determination of the naturally occurring $^{234}$U, $^{235}$U and $^{238}$U nuclides. An ideal yield monitor is $^{232}$U ($t_{1/2} = 72$ years), whose $\alpha$-"peak" is well resolved from those of the three nuclides of interest. Samples should be measured as soon as possible after radiochemical separation, as $^{230}$Th, ingrown from the decay of $^{232}$U, interferes spectrometrically with its $^{232}$U precursor.

2.3 Monitors for the Analysis of Neptunium

The only significant $\alpha$-emitting nuclide of neptunium in the environment is $^{237}$Np. As there is no other $\alpha$-emitting neptunium isotope available, most radiochemical determinations of $^{237}$Np employ the $\beta$-emitter $^{239}$Np ($t_{1/2} = 2.36$ days) as yield monitor. Again, a separate radiometric determination is required, usually by $\beta$-counting, to determine the radiochemical yield (the daughter of $^{239}$Np is a $\gamma$-emitter). The practicalities associated with the use of $^{239}$Np as a yield monitor have been discussed in some detail by Harvey and Lovett. Suffice it to say that $^{239}$Np can readily be obtained by "milking" from a solution of its precursor. $^{241}$Am ($t_{1/2} = 7380$ years), with which $^{239}$Np is in secular equilibrium. Solvent extraction and/or ion exchange can be used to separate $^{239}$Np from $^{243}$Am (see section 4.2.3), at which point the $^{239}$Np is added to the sample as yield monitor. It is imperative that the separation of the two be quantitative and this must be checked each time. Alternatively, $^{233}$Am, with $^{239}$Np in equilibrium, can be added directly to the sample without prior separation. The first approach has the disadvantage of requiring weekly separation and calibration. On the other hand, the second approach relies on the complete elimination of americium in a single analytical step at a precisely determined time.

$^{235}$Np ($t_{1/2} = 396$ days) has been used on occasion as an alternative yield monitor for neptunium analysis. Although its half-life is somewhat longer than that of $^{239}$Np, availability difficulties and the fact that it must be assayed separately by X-ray spectrometry has limited its application.

2.4 Monitors for the Analysis of Plutonium

The three most commonly used yield monitors in the analysis of plutonium are $^{238}$Pu, $^{242}$Pu and $^{244}$Pu. $^{236}$Pu is produced with accelerators by charged particle irradiation of suitable targets, for example, via the reactions $^{234}$U($\alpha$, $2n$)$^{236}$Pu and $^{235}$U(d, $n$)$^{238}$Np($\beta^-$)$^{238}$Pu. The main advantage of this method is that the yield monitor is produced in a pure state, free of other $\alpha$-emitting plutonium nuclides. There are, however, several disadvantages. The $\alpha$-"peak" of $^{238}$Pu lies to higher energy than those of the plutonium nuclides of environmental interest and care must be taken to avoid tailing of the $^{238}$Pu "peak" into that of $^{238}$Pu as a result of overspiking with $^{236}$Pu or poor resolution due to degraded source quality. Further, the short half-life of $^{236}$Pu ($t_{1/2} = 2.85$ years) not only limits its shelf life but also requires the periodic removal of ingrown daughters (i.e. $^{232}$U $\rightarrow$ $^{232}$Th $\rightarrow$ $^{232}$Ra $\rightarrow$ $^{220}$Rn $\rightarrow$ $^{216}$Po $\rightarrow$ $^{212}$Pb $\rightarrow$ $^{212}$Bi), some of which can interfere with both $^{236}$Pu and $^{238}$Pu. Also, its short half-life prohibits its use in mass spectrometric analysis.

$^{242}$Pu is produced by successive neutron capture in $^{239}$Pu, with chemical purification of the plutonium followed by mass separation of the $^{242}$Pu from other isotopes. In contrast to $^{236}$Pu, the $^{242}$Pu tracer is not isotopically pure and corrections, albeit small, must be made for certified impurities of $\alpha$-emitting $^{238}$Pu, $^{239}$Pu, $^{240}$Pu and, if measured, $\beta$-emitting $^{241}$Pu. The $\alpha$-"peak" of $^{242}$Pu lies lower in energy than that of any other $\alpha$-emitting plutonium nuclide of environmental interest and, consequently, moderate overspiking is not a problem. However, underspiking must be avoided as the degraded tails of the unresolved $^{239}$Pu and $^{240}$Pu peaks can contribute to the $^{242}$Pu "peak". The long half-life of $^{242}$Pu ($t_{1/2} = 3.76 \times 10^5$ years) makes it suitable for both radiometric and mass spectrometric measurement, and in practice means that a solution of $^{242}$Pu remains free of daughter impurities for a substantial period of time.

$^{244}$Pu ($t_{1/2} = 8.26 \times 10^7$ years) is also produced by neutron irradiation, but is even more difficult to obtain in a pure state than $^{242}$Pu. Its low specific activity precludes its use in $\alpha$-spectrometry, but makes it very attractive for mass spectrometric analysis.

2.5 Monitors for the Analysis of Americium and Curium

Since americium and curium have very similar chemical properties and do not interfere spectrometrically with each other, they are often analysed together using a single yield monitor, most commonly $^{243}$Am. This approach is valid provided that a radiochemical procedure is employed that does not discriminate between americium and curium at any stage. As in the case of $^{242}$Pu, the $\alpha$-emissions of $^{243}$Am lie lower in energy than those of the americium or curium nuclides of interest, and care must be taken to avoid underspiking which could result in the degraded tail of $^{243}$Am interfering with the $^{243}$Am "peak". The daughter of $^{244}$Am ($t_{1/2} = 7380$ years) is $^{239}$Np ($t_{1/2} = 2.36$ days), a short-lived $\beta$-emitter which, in
turn, decays to $^{239}$Pu. If, as is often the case, the sample is analyzed for both plutonium and americium, the $^{239}$Pu impurity introduced by the addition of $^{243}$Am as yield monitor must be taken into account, as must the $^{241}$Am impurity derived from the decay of the $^{243}$Pu impurity present in the $^{242}$Pu yield monitor.

3 MATRIX PRETREATMENT

3.1 Sampling

The procurement of truly representative samples is a subject in itself and represents, undoubtedly, one of the most difficult and limiting aspects of environmental analysis. The selection of the matrices to be analysed, the sampling methodology to be adopted, the number of samples required, and the sample sizes needed to ensure representativeness are just some of the issues to be considered when planning a sampling campaign. Environmen-
tal materials routinely analysed for actinide nuclides include aqueous samples (e.g. seawater, freshwater, groundwater), soil, sediment, foodstuffs, milk, human and animal tissues, bones, urine, air filters, seaweed, vegetation, etc. Key features of the procedures employed to sample some of these materials are discussed below.

3.1.1 Water Samples

The analysis of actinides in freshwater or seawater requires that a representative sample at a prescribed sampling depth be taken and that the sample remain unaltered until the water is retrieved and treatment commences. For these reasons, all water samplers should be fabricated from clean, inert materials in order to avoid contamination and minimize adsorption on those surfaces in contact with the sample. When sampling deep waters, the sampler should fill or exchange its contents with the surrounding water at the sampling depth and then be sealed completely by a triggering mechanism.

Near-surface samples are often taken from at least 2 m below the surface using peristaltic or deck pumps made from clean, inert materials. Deeper waters are usually sampled using specially designed bottles (e.g. Niskin bottles, Gerard barrels, etc.). The sample volume required for a satisfactory analysis is obviously a function of radionuclide concentration; it may also depend on the nature of the analysis to be performed.

When the separate analysis of suspended particulate and filtered water is required, the samples should be filtered immediately after collection (see section 3.3). Filtered (or, indeed, unfiltered) samples should be stored in poly(vinyl chloride) (PVC) tanks or polyethylene carboys and pretreatment should commence as soon as possible after filtration (sampling) to avoid losses by adsorption onto container walls. Depending on the nature of the analysis, the addition of HCl or other mineral acids and/or more complex mixtures may be required to stabilize the samples.

In order to avoid the disastrous consequences of cross-contamination, the storage tanks should be thoroughly cleaned after use or, where possible, replaced by unused ones. An alternative is to fit disposable polyethylene liners inside the containers. In the case of equipment that, of necessity, has to be reused, care should be taken to clean all surfaces which may have been in contact with the samples as thoroughly as possible before reuse.

Figure 1 Operational principle of (a) grab samplers, (b) piston corers and (c) box corers.
3.1.2 Sediment Samples

Sampling of surface sediments is most frequently done with dredgers or grab samplers. Dredgers, although useful for retrieving coarse sediments and gravels, suffer from severe limitations if representative samples are required. Sediments are collected from a stretch of seabed rather than at a particular point and much of the fine-grained fraction is lost as the dredger is brought to the surface. These problems are partially solved with the use of grab samplers (Figure 1a), which include jaws that drive into the sediment and close, retaining the full sample. However, loss of the fine-grained fraction is not uncommon when complete closure is not achieved due to a shell, pebble or rock fragment becoming trapped in the jaws, and there is little control of the sampling depth. If, as is often the case, preservation of the sediment is a major consideration, coring devices, rather than dredgers and grabs, must be used. The types of corers most frequently employed to sample seabed and lacustrine sediments are the gravity corer, the piston corer and the box corer.

Gravity corers are simple devices, with no moving parts to jam or fail. The penetration of a hollow tube or cylinder into the sediment bed depends only on the weights attached above the tube, and a small hydrographic winch is usually enough for lowering and retrieving such a corer. The base of the coring tube contains an annulus of slightly curved, spring metal fingers which prevents the loss of sample upon pull-out. This is aided by a check valve at the top of the corer, which allows water to flow through the barrel as it penetrates the bed and which closes upon retrieval. The operational principle of the piston corer is quite different from that of the gravity corer, in that the sampling barrel in a piston corer is activated and driven into the bed by an automatic ejection mechanism after the surface of the bed has been reached (Figure 1b).

Box corers consist of a weighted cubic box, mounted on a housing frame, which is allowed to sink into the sediment, again with the assistance of weights. At this point, a forked arm is triggered which pivots underneath the bottom of the sampling box, enabling the retrieval of a large quantity of practically undisturbed sediment (Figure 1c). Back on deck, subsamples may be taken by driving hollow PVC tubes vertically through the retrieved sediment “monolith”. For more comprehensive and detailed descriptions of sediment sampling techniques, the reader is referred to McQuillin and Ardus, Moore and Heath, and Stowe.

Sediment cores must be extruded and sectioned as soon as possible after recovery. It is recommended that an outer annulus or rind of sediment be removed from each section or layer in order to eliminate contamination due to smearing, which is difficult to avoid during sampling and extrusion.

3.1.3 Soil Samples

If, as is often the case, soil samples are used to estimate accumulated deposition from, for example, global fallout, sampling should be carried out in open, flat, undisturbed areas. Meteorological conditions, vegetation and human/animal activity should be carefully considered when selecting a particular site. In the case of contaminated sites, systematic sampling should be carried out to establish the distribution pattern of the contamination. The type of sampling device or approach used clearly depends on the characteristics of the soil in question (e.g. granulometry, porosity, moisture content, mineralogical composition, etc.). Coring is the preferred method for cumulative deposition studies. The main limitation is, of course, the presence of large quantities of stones, roots or other material which hamper the penetration of the corer to the required depth. In these cases, alternative methods such as scooping within a defined template are recommended. A detailed description of these methods can be found in Chieco.

3.1.4 Biological Samples

In the case of biological samples (including foodstuffs, marine and terrestrial vegetation, human and animal bones, tissues, urine, etc.), the amount of material available is generally larger than that required for analysis and, thus, care must be taken to ensure that a representative subsample is acquired. This can be achieved by homogenization of a large or composite sample prior to subsampling. Replicate analyses should be carried out to demonstrate the adequacy of the homogenization and subsampling methods employed.

Wet and dry ashing techniques, described below, are normally used to eliminate organic matter as samples in an inorganic form are more readily solubilized.

3.2 Sample Preparation

Sample preparation covers all the preparatory steps that must be carried out prior to chemical separation and purification. Importantly, these steps include the complete homogenization of the sample as well as the equilibration (isotopic exchange) of yield monitor(s) with determinand(s) and, in certain cases, the stabilization of their respective oxidation states.

In the case of water samples, the initial step in the analysis is designed to achieve full equilibration between determinand(s) and yield monitor(s) prior to preconcentration. This is particularly important for multivalent actinides such as plutonium, which normally present in aqueous media as a mixture of oxidation states exhibiting quite distinct sorption/coprecipitation properties. The most common method of achieving...
equilibration is by immediate acidification of the sample, followed by the addition of a reducing agent such as Na$_2$SO$_3$\(^{24}\) or Na$_2$S$_2$O$_5$\(^{25}\). Appropriate quantities of yield monitor(s) and carrier(s), for example Fe, Mg, Ca, Mn, are added and the sample is mixed for several hours to ensure thorough homogenization. If the suspended particulate phase and the solution phase are to be analyzed separately, filtration should be carried out immediately after sampling and prior to acidification.

In the case of urine samples, equilibration between determinand(s) and yield monitor(s) is achieved by, for example, acidification with aqua regia and the repeated addition of H$_2$O$_2$ in the course of wet ashing (see section 3.4.2.2).

Solid samples such as soil, sediment and biota are normally dried in an oven to constant weight, ground, blended or milled to a fine powder, and thoroughly mixed to ensure homogeneity. In some cases, a defined heating cycle is recommended.

3.3 Filtration/Ultrafiltration

Microfiltration is the process of removing particulate matter from aqueous or gaseous samples by passage through a microporous medium such as a membrane filter. Although micrometer-sized particles can also be removed by the use of nonmembrane or depth filters, that is fibrous media, only a membrane filter having a precisely defined pore size can ensure quantitative retention. Screen filters are so named because they retain particles on the surface of the membrane through which the aqueous (or gaseous) sample is forced to pass. High quality filters are readily available from a number of leading manufacturers.

In the case of water, it has become conventional to define the suspended particulate phase as the material retained by a 0.45-μm pore-size filter. This is, however, an operational cut-off, since a variety of smaller particles and colloids are known to be present in great abundance in all natural waters\(^{26-28}\). When the analysis of smaller particles in the colloidal-size range is required, these particles can be concentrated by, for example, tangential-flow ultrafiltration using polysulfone membrane cassettes with nominal molecular weight limits (NMWLs) as low as 0.8–1 kDa (1 kDa ~ 1.2 nm).

The ultrafiltration assembly is normally operated in concentration mode. In this mode, macromolecules and colloids are retained by the membrane, flowing tangentially across its surface and returning to the original sample container, the contents of which are referred to as the retentate. Molecules and particles smaller than the pore size (NMWL) of the membrane are able to pass through it and these (the permeate) are directed to a separate container. Both fractions can then be treated separately in the same manner as filtered water.

3.4 Preconcentration

Following the sample preparation stage, samples are usually preconcentrated to reduce bulk or volume, after which the separation chemistry can commence. Preconcentration may involve the ashing of solid samples to remove organic material, the evaporation of liquid samples to reduce their volume, the acid leaching of solid samples followed by evaporation of the leachates, bulk coprecipitation, etc.\(^{29}\). Since the actual steps involved depend on the type of matrix being processed, and these are numerous, we have confined ourselves here to some examples chosen to highlight the preconcentration steps required for the assay of actinides in some of the most frequently analyzed materials, namely water, sediment, soil and biological matter. The reader should, nevertheless, note that alternative or additional steps may be required for certain other types of matrices (e.g. urine, bone, etc.), the details of which have recently been reviewed elsewhere\(^{17,23}\).

3.4.1 Preconcentration of Aqueous Samples

One of the difficulties associated with the analysis of actinides in sea- and freshwater is the requirement, more often than not, to process large volumes in order to achieve the required analytical precision. The logistic and practical problems associated with the handling and in situ processing of large volumes should not be underestimated. Numerous techniques have been proposed over the years for the preconcentration of actinides from large volumes of water. These are generally based on the coprecipitation of actinides with suitable carriers or their in situ sorption onto mineral surfaces.

3.4.1.1 Actinide Preconcentration by Coprecipitation

Although a variety of methods have been developed based on coprecipitation with, for example, manganese dioxide\(^{30}\), magnesium hydroxide\(^{31}\), bismuth phosphate\(^{32,33}\), and ferrous hydroxide\(^{34,35}\), coprecipitation of actinides with ferric hydroxide is most widely used, particularly for transuranium analyses\(^{36-41}\). In essence, the previously filtered (or, sometimes, unfiltered) sample is acidified with 12 M HCl to pH ~ 1.6. Upon the addition of appropriate amounts of yield monitor(s), reducing agent(s) and Fe\(^3+\) carrier (>1 mg per litre of sample), the sample is vigorously stirred for at least 3 h in order to ensure complete equilibration. The coprecipitation of the actinides with ferric hydroxide is achieved by adjusting the pH of the sample to between 7.5 and 8.0 using sodium hydroxide or ammonia. Care must be taken during the pH adjustment to prevent the formation of insoluble calcium and magnesium carbonates. The sample is left to settle overnight (~12 h) and the Fe(OH)$_3$ precipitate, containing the actinide nuclides, is collected.
by filtration through, for example, a cellulose nitrate screen filter. The filter is then dissolved in a concentrated solution of HNO₃ and HCl (e.g. 1:1 by volume), the solution evaporated to dryness and the residue, after conversion to nitrate or chloride form, redissolved in the appropriate medium for further purification.

The ferric hydroxide coprecipitation method cannot be used if the analysis of neptunium is also a requirement. In aqueous solution, neptunium is present as the pentavalent neptunyl ion, which is soluble even at alkaline pH and does not coprecipitate with ferric hydroxide. In this case, an alternative coprecipitation step, such as coprecipitation with barium sulfate following reduction with ferrous ammonium sulfate, is recommended.

3.4.1.2 Actinide Preconcentration by In Situ Sorption onto Metal Oxides There are obvious practical difficulties in separating radionuclides from large volumes of water, as we have already noted. However, a number of techniques for the in situ separation of specific radionuclides from bulk samples have been developed over the years, which obviate the need to collect and store large volumes. All of these methods have one thing in common in that the sample is pumped quickly through a cell or sampler containing a chemical agent which separates the radionuclide of interest from the bulk liquid.

Sorption on, for example, manganese dioxide or aluminum oxide has been used to preconcentrate actinide elements from large volumes of water. Sorption samplers capable of processing up to 4000 L of water with a single cartridge (or charge) have been developed which removes the need to collect and transport large volumes of water while, at the same time, providing a substantial improvement in analytical precision due to the larger volumes that can be processed in relatively short periods of time. Problems such as sample deterioration during handling and storage are virtually eliminated, as the sampler operates on water pumped directly from the water body in question.

Caution, however, should be exercised when using sorption samplers, as laboratory and field tests have shown that actinide retention by these systems is not necessarily quantitative. In experiments using Al₂O₃ as the sorbing agent, Nevissi and Schell demonstrated that while ²⁰⁷Bi, ²¹⁰Po, ¹⁵⁵Eu and ²⁴¹Am were quantitatively retained on a single sorption bed (200 mesh Al₂O₃ powder, ~6 mm thick), ⁶⁰Co and ²³⁹,²⁴⁰Pu were not. To quantify ⁶⁰Co and ²³⁹,²⁴⁰Pu, both of which exist in natural waters in more than one valence state simultaneously, it proved necessary to pass the sample through a set of three (or more) beds arranged in series and to measure the retention of both nuclides on each of the beds. Clearly, the viability of the sorption cell approach is based on the assumption that none of the radionuclide of interest is present in a nonsorbable form. There is evidence to suggest that this is not always the case.

3.4.2 Dry and Wet Ashing/Fusion

Fundamental to any radiochemical analysis is the need to prepare the analyte in a form suitable for separation chemistry, ideally, fully dissolved or solubilized. A combination of dry and wet ashing greatly facilitates the leaching of soluble components from a solid matrix, in that any organic matter present is readily eliminated and adsorbed radionuclides can be taken into solution. Accordingly, dry and wet ashing are usually the first operations to be carried out in most radiochemical separations. Experience, however, shows that dry and wet ashing, on their own, are seldom sufficient to completely solubilize a sample, and additional steps may have to be employed, particularly in the case of samples containing actinides in a refractory form.

3.4.2.1 Dry Ashing

Dry ashing is normally the first preconcentration step in treating biological samples such as seaweeds, soft animal tissues and bones. Its main purpose is the oxidation of organic matter by slow combustion, until the sample is converted into a nonvolatile inorganic residue comprising metallic oxides as well as nonvolatile phosphates, silicates and the like.

In the course of dry ashing atmospheric oxygen acts as an oxidizing agent, converting organic carbon into CO₂. Some elements are prone to volatilization, especially when certain other species are present in the matrix. For example, the chloride ion can react with lead producing volatile components such as PbCl₂. Moreover, if polonium is present, it can be volatilized very easily given its low melting point of 254 °C. Consequently, volatilization must be guarded against when carrying out certain analytical determinations.

Preparatory to dry ashing, an appropriate quantity of sample is dehydrated at a suitable temperature (traditionally 105 °C, though temperatures as low as 80 °C have become common) to constant mass in a ventilated oven (this step is necessary to determine the dry mass of the sample, which is the reference mass to which the mass activity of the analyte is normally referred). Following this, an accurately measured quantity of the appropriate yield monitor is added by pipetting little droplets of the solution as evenly as possible over the surface of the sample and gently drying under an infrared lamp.

Dry ashing is effected by placing the sample in a preweighed porcelain crucible and heating it (partially covered) in a muffle furnace while slowly raising the temperature from approximately 150 to 500 °C in, for example, 50 °C increments over a period of 48 h. Ashing is continued until a powdery, white ash forms, indicating...
the complete removal of carbon. The additional time necessary for this process is typically about 24 h.\textsuperscript{(17,55)} Upon completion of the ashing process, the sample is weighed again, this time to determine the ash weight. Nonreproducibility in the dry weight to ash weight ratio for a set of similar samples is a useful indicator of possible losses due to deflagration in the course of combustion.

Dry ashing is advantageous in that it provides a simple means of substantially reducing sample bulk (a factor of between 4 and 10 is typical for soft tissues). However, it is not to be recommended if the nuclides of interest are volatile at ashing temperatures. A good example is the measurement of $^{210}\text{Po}$ in shellfish, where the edible portions should only be wet ashed. Dry ashing should not lead to any significant losses in the case of the actinides, all of which have melting points above 500°C.

A complication arises from the fact that reactions can take place within the ash at high temperatures which result in the formation of refractory metals and other refractory compounds. Violent ignition of the sample surface may produce such high temperatures. Since the actinides are known to form refractory oxides at these temperatures, it is recommended that the temperature of the furnace be increased very slowly in order to prevent sudden ignition bursts. Equally, the furnace temperature should not be allowed to exceed 550°C.

### 3.4.2.2 Wet Ashing

Wet ashing is a very useful method to be applied in cases where the organic content of the sample is not too high (e.g., mineral-rich sediments or previously dry-ashed samples). The technique can also be used to digest precipitates retained by cellulosic microfilters simply by wet ashing the filters together with their contents. Although it is a more tedious procedure than dry ashing, it is often preferred as there is little or no risk of volatilization and refractory compound formation. Moreover, yield monitors and carriers can be added directly to the solution, becoming rapidly equilibrated with indigenous ions in the course of the (wet) ashing process.\textsuperscript{(17,54–58)}

Decomposition and dissolution of samples by wet ashing occurs because most electropositive metals, as well as many metal oxides, carbonates, sulfides, etc., are soluble in dilute acids. More electronegative metals and some of the commonest minerals (e.g., aluminates, silicates) require treatment with hot concentrated mineral acids, which provide the necessary high proton concentration.\textsuperscript{(54)}

The most commonly used reagent in wet ashing is concentrated (16 M) HNO$_3$. Given its high oxidizing power and acid strength, most digestions can be carried out using this reagent alone. Alternatives include concentrated (12 M) HCl, a mixture of three parts of 12 M HCl to one part of 16 M HNO$_3$ (aqua regia),\textsuperscript{(41,59)} or 40% HF.\textsuperscript{(60)}

The oxidizing power of these acids can be enhanced by the addition of small volumes of H$_2$O$_2$ during the digestion process.\textsuperscript{(61,62)}

Hydrofluoric acid is a weak, nonoxidizing acid. However, the fluoride ion is a most powerful complexing anion, capable of combining with refractory elements to the point of making them soluble. The main application of HF is the solubilization of siliceous materials by volatilization of silicon as SiF$_4$ while the rest of the matrix is brought into solution. For this reason, HF digestion is an appropriate procedure with which to treat soil samples from nuclear bomb test sites, where plutonium and americium may have become incorporated in silicates and polysilicates during the explosion/fireball. In addition, when using HF as a digestant, uranium in a hexavalent state can be eliminated following the formation and volatilization of UF$_6$. There are, however, certain difficulties associated with the use of HF, including the requirement to use poly(tetrafluoroethylene) (PTFE) or platinum beakers instead of borosilicate glass vessels, the need to remove completely the fluoride ion after digestion in order to prevent it from interfering at a later stage in the radiochemical analysis, and the high toxicity of this acid.

When the complete oxidation of organic matter that proves resistant to digestion by the means outlined above is desired (e.g., lipids), treatment with small additions of hot concentrated (98%) H$_2$SO$_4$ is recommended (H$_2$SO$_4$ is a very strong oxidizing agent, which possesses powerful dehydrating properties). In addition, the digestant can be heated to relatively high temperatures by virtue of the higher boiling point of H$_2$SO$_4$ compared to that of HNO$_3$ or HCl. However, its use is not recommended in the presence of significant quantities of Ca, Sr, Ba and Pb, as they can form sparingly soluble (CaSO$_4$) or totally insoluble (SrSO$_4$, BaSO$_4$ and PbSO$_4$) sulfates. In these cases, an alternative procedure is to use perchloric acid (HClO$_4$), which dissolves most metals and alloys. However, potassium, rubidium and cesium perchlorates are insoluble in aqueous solution, and the use of concentrated HClO$_4$ is restricted by the ever-present risk of explosion.

Various wet ashing procedures, applicable to different sample matrices, have been described in detail in the literature.\textsuperscript{(17,56,60–63)} Here, we shall confine ourselves to a typical methodology which has proved its worth in our laboratory.

Wet ashing of biological samples follows immediately upon dry ashing. Spiked samples are removed from the muffle furnace and allowed to cool to room temperature in their original crucibles. Each sample is transferred to a beaker containing 16 M HNO$_3$ (typically 100 mL). The crucible is rinsed twice with 16 M HNO$_3$, and the rinses added to the beaker, which is transferred to a hot plate.
The mixture is then boiled under reflux (i.e. covered with a watch glass to minimize evaporation) and stirred using a Teflon-coated magnetic stirring bar. Small additions of \( \text{H}_2\text{O}_2 \) are made regularly during the digestion, which is allowed to proceed for a minimum of 6 h. The watch glass and the magnetic stirrer are removed and the sample is evaporated to near dryness. The presence of unoxidized organic matter is evidenced by the evolution of brown fumes and the formation of a black residue. The further addition of small quantities of 16 M \( \text{HNO}_3 \) and \( \text{H}_2\text{O}_2 \), and repeated evaporation to dryness until the residue appears to be almost pure white, is sufficient to eliminate residual organic matter. The sample can now be redissolved in 100 mL of 8 M \( \text{HNO}_3 \). It is our practice to microfilter the sample at this stage prior to purification by solvent extraction or ion exchange.

The digestion procedure for sediments and soils is somewhat simpler. A small quantity of sediment (10–20 g) is dried at 105°C to constant mass and digested with 100 mL of hot aqua regia spiked with appropriate yield monitors. After a minimum of 6 h of continuous leaching, the sample is allowed to cool to room temperature and the solid residue is removed by microfiltration. The filtrate is evaporated to dryness and, after conversion to nitrate form, re-dissolved in 8 M \( \text{HNO}_3 \), at which stage it is ready for further purification. Note that this procedure does not involve the complete dissolution of the sample; it is designed purely to leach actinides that have been (weakly) adsorbed on the surface of sediment particles, as opposed to actinides incorporated within the mineral lattice.

Heated pressure vessels and microwave digestion units are being used increasingly to accelerate the digestion and to achieve the complete dissolution of small (gram-sized) samples. (64–68)

The digestion of soil samples containing actinides in a refractory form requires a more aggressive attack, which can be achieved by digesting the samples in a mixture of 40% HF and 16 M \( \text{HNO}_3 \), 1:3 by volume. HF provides the complexing anion necessary to break down silicate compounds, while \( \text{HNO}_3 \) provides the oxidizing power. As stressed above, digestions must be carried out in PTFE or platinum-coated dishes. Upon completion of the process, samples must be evaporated fully to dryness and converted to the nitrate form. Re-dissolution in 8 M \( \text{HNO}_3 \), followed by filtration, should be carried out in order to obtain a clear/pure solution suitable for further processing.

Certain precipitates, for example Fe(OH)\(_3\), can usually be dissolved in 16 M \( \text{HNO}_3 \) after a 6-h digestion, as described above for biological samples. However, dissolution of other precipitates, such as NdF\(_3\), can be quite difficult, particularly when large quantities of precipitate are involved (e.g. plutonium chemical speciation analysis; see section 5), as NdF\(_3\) is practically insoluble in concentrated \( \text{HNO}_3 \). Nevertheless, Lovett and Nelson (69) have reported that the dissolution of small quantities of NdF\(_3\) can be effected with ~70 mL of 16 M \( \text{HNO}_3 \) to which a small quantity of boric acid (\( \text{H}_3\text{BO}_3 \)) and an equal volume of deionized/distilled water have been added.

### 3.4.2.3 Fusion

Total dissolution of mineral or biological samples is indicated in cases where actinides are known to be present in a refractory form as a result of their exposure to high temperatures, or where they are mixed with Cr, Si and Fe oxides which are intractable to normal dissolution. In such cases, low and erratic recoveries and nonreproducible results are likely when using wet ashing as the sole solubilization technique. The lack of reproducibility arises from the failure to achieve isotopic equilibrium between monitor and determinand. (70)

For a comparison of wet ashing and fusion techniques in the determination of actinide radionuclides, the reader is referred to a specific study of this topic by Smith et al. (71)

One of the most commonly employed fusion methods involves the use of a potassium fluoride/pyrosulfate solution (72–74) in order to volatilize silica as SiF\(_4\). Another technique is based on the dissolution of mineral samples with lithium metaborate. (75) The potassium fluoride/pyrosulfate fusion is carried out by sprinkling 3 g of anhydrous potassium fluoride over a 0.5-g sample of analyte, previously digested in a mixture of 0.5 mL of 16 M \( \text{HNO}_3 \) and 3 mL of 48% HF. The resulting “cake” is melted over a blast burner until a clear solution is obtained. Following cooling, 3.5 mL of concentrated \( \text{H}_2\text{SO}_4 \) are added and the solution heated until all the fluoride gases have been expelled. Upon the appearance of fumes of SO\(_3\), the sample is treated with 2 g of sodium hydrogen sulfate in order to obtain a clear pyrosulfate solution. The latter is evaporated to near dryness, the residue re-dissolved in diluted HCl and then treated as described in section 3.4.3 below.

In the lithium metaborate fusion method, 2 g of spiked sample are combined with 6 g of LiBO\(_2\) in a graphite crucible and heated at 950°C for 30 min. Upon cooling, the LiBO\(_2\) – silicate mixture thus formed is immediately dissolved in 1 M \( \text{HNO}_3 \), at which point it also can be coprecipitated as described below.

### 3.4.3 Coprecipitation

Following leaching or dissolution, the sample is filtered and the filtrate, containing the actinides of interest, is converted to the appropriate medium for a coprecipitation step in which these actinides are not only further preconcentrated but also purified from other leached elements such as the alkalis and alkaline earths. Coprecipitation either with Fe(OH)\(_3\) in an alkaline medium (36,38,76) or
with calcium oxalate in an acidic medium at a pH between 1.5 and 4.5(39,62,77,78) is often used. The latter is recommended for samples with a high calcium or phosphate content (e.g. bone), in which case the actinides do not coprecipitate efficiently with Fe(OH)₃. Actinides can also be coprecipitated with rare-earth fluorides such as LaF₃, NdF₃ and CeF₃(80,81) and with bismuth phosphate(82) and barium sulfate.(83,84)

To illustrate, consider the case of coprecipitation with ferric hydroxide. Here, the sample in solution is transferred to a beaker and an appropriate quantity of Fe³⁺ carrier (100 mg) added if necessary. This step may be omitted in the case of soils and sediments, as they already contain enough natural iron (in the case of water, which may have been treated at an earlier stage with iron or neodymium, further addition of carrier is unnecessary). Coprecipitation is effected by slowly adding an appropriate quantity of 35% ammonium hydroxide solution to the sample with constant stirring until a flocculent mass of brown Fe(OH)₃ precipitate is formed.(86) After adjusting the pH to at least 8, the sample is allowed to stand for 2 h at room temperature prior to centrifugation. The supernatant is discarded and the precipitate dissolved in a small quantity of either 16 M HNO₃ or 12 M HCl, depending on the purification procedure to follow. It is then evaporated to dryness and re-dissolved in 100 mL of the appropriate medium (e.g. 8 M HNO₃, 9 M HCl, 1 M HNO₃ – 90% methanol) prior to further purification.

4 RADIOCHEMICAL SEPARATION AND PURIFICATION

Although the sample pretreatment steps described above separate the actinides of interest from the bulk matrix, a large number of potential interferants (i.e. stable elements and natural or artificial radioelements) are still present in solution along with the actinides and must be removed if high quality, undegraded sources are to be obtained. Over the years, various separation schemes, primarily based on the use of ion exchange and solvent extraction techniques, have been proposed and adapted for different matrices and types of analyses.

4.1 Ion Exchange

The separation by ion exchange of actinides from other elements and from each other is based on differences in their sorption characteristics on conditioned ion exchange resins. Exchange resins are insoluble porous lattices with attached ionic functional groups linked to exchangeable counterions of opposite charge.(85) The charge of the functional group dictates whether the resin will act as a cation or anion exchanger. During the ion exchange process, when resin and sample are put in contact, counterions are replaced by sample ions having the same charge. Neutral molecules and those having the same charge as the functional group are not retained and pass through the resin without adsorption. The exchanged ions can selectively be desorbed by the introduction of an ion of higher affinity for the exchangeable sites or a high concentration of an ion of equivalent or lower affinity.

Typical cation exchange resins are formed from a cross-linked styrene–divinylbenzene copolymer with attached anionic functional groups, for example SO₃²⁻, which forms the well known AG 50 W cation exchanger (1). Attached to the functional group are exchangeable counterions opposite in charge to that of the functional group. The counterion is normally H⁺, thus forming the sulfonic acid group SO₃H⁻ with the functional group SO₃²⁻. Counterions are substituted by similarly charged sample cations during the cation exchange process because the counterions have a lower selectivity for the resin’s functional groups than the sample ions to be sorbed. The cation exchange process can be summarized by Equations (1) and (2):

\[
zR - SO_3H + Me^{z+} \rightleftharpoons Me(R-SO_3)_z + zH^+ \tag{1}
\]

\[
\frac{[Me(R-SO_3)z][H^+]}{[R-SO_3H]^z[Me^{z+}]} = K_c \gg 1 \tag{2}
\]

where z is the electric charge of the sample ion Me and R symbolizes the styrene–divinylbenzene organic group.

Many of the features described above are common to cation and anion exchange resins. The fundamental difference between a cation and an anion exchanger is that, in the latter case, the styrene–divinylbenzene copolymer is derivatized with a cationic functional group, for example, CH₂N(CH₃)₃, forming the AG 1 anion exchanger (2). Anion exchange resins are normally available in two ionic forms, namely the nitrate form with NO₃⁻ as the counterion and the chloride form with Cl⁻ as the counterion. Conversion from one form into the other is usually achieved by gently washing the resin with an HCl or HNO₃ solution of the appropriate concentration.
where the concentration of Me$_2$ is not favored at high proton concentrations, as shown by Equation (3)

\[ 2R - SO_3H + Me^{2+} \rightleftharpoons Me(R - SO_3)_2 + 2H^+ \quad (3) \]

is not favored at high proton concentrations, as shown by Equation (4)

\[ [Me(R - SO_3)_2] = \frac{K_c[R - SO_3H]^2[Me^{2+}]}{[H^+]^2} \overset{\text{constant}}{=} \frac{[H^+]^2}{K_c[R - SO_3H]^2[Me^{2+}]} \quad (4) \]

where the concentration of Me$_2^+$ can be considered constant by virtue of its continuous supply while the sample is being passed. Thorium can be eluted from the column with 0.75 M oxalic acid ($C_2H_2O_4$)$_2$. (60)

4.1.2 Separation of Uranium by Ion Exchange

Separation of uranium from other actinides by anion exchange is based on its different sorption behavior in HNO$_3$ and HCl media. (60,87) In HCl medium (9 M), uranium (together with plutonium, neptunium, polonium and iron) is strongly adsorbed as the complex anion $UO_2Cl_4^{2-}$, while thorium and trivalent actinides pass through the column without adsorption. Elution of uranium is achieved using a 7–8 M HNO$_3$ solution. In this medium, uranium is not retained by the column, whereas plutonium and neptunium are.

A difficulty associated with this procedure is the coelution of iron and polonium with the uranium fraction. To avoid problems associated with excessive iron at the source preparation stage and the presence of spectrometrically interfering polonium isotopes, the three elements are eluted sequentially using appropriate column volumes of 7–8 M HNO$_3$. (88) Iron is eluted first, followed by uranium and, finally, polonium. Alternatively, iron can be removed from the column (together with plutonium) by reducing these elements with iodide. (89) When co-eluted with a single HNO$_3$ wash, uranium and iron are often separated from each other by solvent extraction with isopropyl ether from an 8 M HCl medium. (60)

Iron can also be separated from uranium by sorption of uranium onto an anion exchange resin from an ammonium acetate medium at pH 4.5–5.0. (80) In this medium, iron passes through the resin without adsorption, while uranium is retained. Uranium can then be eluted with dilute HCl.

4.1.3 Separation of Neptunium by Ion Exchange

The levels of neptunium (in reality $^{237}$Np) in the environment are low compared with those of most other actinides. This probably explains why comparatively few papers have been published over the years on methods for the assay of neptunium in environmental matrices. (9–11, 91–93) When $\alpha$-spectrometry is used to determine $^{237}$Np at trace level, the key step is the purification of $^{237}$Np from other interfering nuclides and, in particular, from $^{234}$U, $^{231}$Pa and $^{230}$Th.

For example, Yamamoto et al. (9) improved on the method of Sakanoue (94) (which is based on solvent extraction of neptunium with tri-$\alpha$-octylamine (TOA) and its coprecipitation with LaF$_3$) by introducing further purification steps involving anion exchange. In this method, neptunium(IV) is adsorbed from an 8 M HNO$_3$ medium saturated with Al(NO$_3$)$_3$. The column is washed successively with 8 M HNO$_3$, 10 M HCl and 0.1 M HI–10 M HCl to remove uranium, thorium and plutonium, respectively. Finally, neptunium is eluted from the column with 4 M HCl. Further purification (in order to eliminate any remaining traces of $^{234}$U) can be effected by converting the eluate from the previous column to a 4 M $C_2H_2O_4$ medium and passing it through a column of AG 1 anion exchange resin (acetate form). In this medium, neptunium is not adsorbed on the column, whereas uranium is strongly sorbed. (9)
In an alternative approach, favored by Schell and Tobin, neptunium is sorbed, together with plutonium and thorium, from an 8 M HNO₃ medium and, after the elimination of thorium and plutonium by rinsing with 9 M HCl and 0.1 M NH₄I–10 M HCl, respectively, eluted with 3 M HCl and a few drops of HF.

4.1.4 Separation of Plutonium by Ion Exchange

Although plutonium is readily sorbed on both cation and anion exchangers from acidic media, anion exchange from a nitric or hydrochloric medium provides the most efficient way to separate this element from other actinides and has been adopted in the majority of separation schemes published in the literature. Indeed, the strong tendency of plutonium to form anionic complexes, the variation in the stability of these complexes with oxidation state and the reluctance of most metals to form anionic complexes, make it possible to separate plutonium from many impurities by adsorbing it as an anionic complex and then selectively desorbing it by controlling the acid concentration and eluant composition.

Plutonium in all valences and concentrations is readily adsorbed onto cation exchange resins from acidic solutions. However, the degree of adsorption varies depending on the oxidation state of plutonium (decreasing in the order Pu(IV) > Pu(III) > Pu(VI)) and the acid concentration (decreasing with increasing acid molarity). The common practice is, therefore, to adsorb plutonium from relatively dilute acid and elute it with a concentrated one. Mathew et al. used this approach to separate plutonium from bismuth introduced via a bismuth phosphate coprecipitation step. Plutonium was sorbed from 0.75 M HCl medium onto a Dowex 50 WX-8 resin (H⁺ form), while Bi³⁺ and the alkalis and alkaline earths passed through without adsorption. Plutonium was then eluted with 12 M HCl and further purified by anion exchange.

As we have noted above, the most widely used separation schemes are based on anion exchange from HCl or HNO₃ medium. From the former, plutonium is adsorbed as the PuCl₆²⁻ species. An efficient separation of plutonium can be achieved by adsorption from 9 M HCl. In this medium, Pu(IV), Np(IV) and U(VI) are strongly sorbed, while Th(IV) and trivalent actinides pass through the column without adsorption. Iron and polonium, which also form anionic complexes in this medium, are co-adsorbed along with plutonium. After the column is rinsed with 9 M HCl in order to remove nonadsorbed elements from the dead volume, iron, uranium and polonium are sequentially stripped using 7.2–8.0 M HNO₃. Elution of plutonium is then achieved using an appropriate eluant. Although 1.2 M HCl–0.7% H₂O₂ is widely used, alternative eluants must be employed if pure solutions of plutonium are required, as in this medium neptunium is co-eluted along with plutonium. Selective desorption of plutonium has been achieved using 9 M HCl–0.05 M NH₄I or 6 M HCl–0.25 M HF. The iodide ion in strong hydrochloric media reduces plutonium from the tetravalent to the trivalent state. In the trivalent state, plutonium does not form anionic complexes and is released from the column, while Np(IV) and U(VI) remain adsorbed.

A similar scheme is appropriate for the purification of plutonium from a nitric medium (normally 8 M HNO₃). In this medium, tetravalent plutonium is left as the hexanitratoto complex, Pu(NO₃)₆²⁻, readily exchangeable on the anion exchange column, while iron, trivalent actinides, uranium, the bulk of rare earths and divalent metals (unable to form anionic complexes) pass through without being adsorbed. Neptunium and thorium, which do form anionic complexes, are co-adsorbed along with plutonium. Separation of thorium from plutonium is achieved by rinsing the column with a moderately concentrated (7–8 M) solution of HCl (thorium is not adsorbed in this medium and, thus, is eluted from the column). As in the previous scheme, several solutions can be used to elute plutonium, such as 12 M HCl–0.1 M NH₄I, 10 M HCl–0.1 M H₂SO₄, 0.36 M HCl–0.01 M HCl and 0.35 M HNO₃. Finally, if required, neptunium can be eluted from the column with, for example, 1 M HCl.

4.1.5 Separation of Americium and Curium by Ion Exchange

Transplutonium elements such as americium and curium can be preconcentrated in strongly basic cation exchangers from dilute solutions of HCl or HNO₃ or from 2–6 M HCl in the presence of at least 40% alcohol. Unfortunately, the large number of other elements co-adsorbed with these radioelements effectively limits the use of cation exchangers to the preconcentration stage rather than the purification stage. Nevertheless, good separation of the transplutonium elements from the lanthanides (but not from other elements) has been achieved by sorption in a 1 M HCl medium and elution with 6 M HCl. Under these conditions, americium and curium are rapidly eluted from the column, while the lanthanides are only very slowly separated.

Separation of certain actinides from lanthanides can be achieved using cation exchangers at high temperatures and complexing agents such as lactic acid or α-hydroxyisobutyric acid. However, this technique requires sophisticated equipment and is not practical for the routine analysis of environmental samples. Anion exchange represents a much simpler and more versatile alternative.
Transplutonium elements are only slightly sorbed on anion exchangers in dilute mineral acid media. However, they are strongly sorbed from solutions containing 80–90% alcohol at acid concentrations of 0.1–1 M. This property has been used to separate americium and curium from other elements which are poorly sorbed under these conditions. (i.e. elements with Z < 56, as well as Hf, Ta, Re, U and Np). The most effective results have been obtained with solutions of methanol containing HNO₃. For example, Guseva et al. used 0.5 M HNO₃–95% methanol, while other authors have employed 1 M HNO₃–93% methanol or 1 M HNO₃–90% methanol. (Pu(IV), Th(IV), Pb(II) and Bi(II), which also have high distribution coefficients in this medium, are co-adsorbed with the transplutonium nuclides and, accordingly, are normally separated prior to this step. Lighter lanthanides are also co-adsorbed, but heavier lanthanides (above gadolinium) pass through without sorption. Unfortunately, some of the lighter lanthanides (i.e. cerium, lanthanum and neodymium) dominate the total lanthanide content of most environmental samples and an additional purification step must be included in order to eliminate them. One such step is to rinse the column with an ammonium thiocyanate solution in methanol or, alternatively, to pass the sample through a second anion exchanger in nonaqueous HCl–methanol medium.

Americium and curium are finally co-eluted using 1.5 M HCl–86% methanol, or 0.5 M HNO₃–80% methanol or 8 M HNO₃. The use of HCl–methanol has the added advantage of not eluting any traces of Pu, Po, Th, U, Bi and Pb that might still be on the resin.

4.2 Solvent Extraction

Solvent extraction techniques are based on the capacity of different elements to form stable complexes with organic ligands. The resulting complexes are insoluble in water, but readily soluble in benzene, xylene, cyclohexane, carbon tetrachloride, n-heptane and other organic solvents. When nonmiscible aqueous and organic phases are equilibrated with each other, these large nonpolar or weakly polar uncharged complexes are preferentially transferred from the aqueous to the organic phase, while uncomplexed elements remain in the aqueous phase.

The extractability of the actinides diminishes as a function of valency in the sequence IV > VI > III > V and, for this reason, actinides are usually extracted in the tetravalent state. The efficiency of the extraction also depends on the acidity of the aqueous phase. By varying the acidity and composition of this phase, selective extraction of actinides and other elements which form complexes of differing stabilities can be effected.

Solvent extraction of actinides is usually carried out by means of an organic complexing agent in combination with an organic solvent. The choice of complexing agent depends on the nature of the element to be extracted and includes: amines such as trilauryl amine (TLA), TOA, tri-iso-octylamine (TIOA) and methyl-tri-capryl ammonium chloride (Aliquat-336); organophosphorus compounds such as di-2-ethyl hexyl phosphoric acid (HDEHP), tri-n-octyl phosphine oxide (TOPO), tri-n-butylphosphosphate (TBP) and dibutyl-N,N-diethyl carbamyl phosphate (DDCP); and other compounds such as β-diketone thienyl trifluoroacetone (TTA) and ethylenediaminetetraacetic acid (EDTA).

4.2.1 Separation of Thorium by Solvent Extraction

As in the case of ion exchange, the inability of thorium to form stable chloride complexes has been used to separate thorium from iron and other actinides by solvent extraction. In a separation scheme using TIOA in xylene (1:9 by volume), thorium in an 8 M HCl medium remains in the aqueous phase, together with trivalent actinides, while plutonium and neptunium are extracted into the organic phase. Following contact of the aqueous phase with TOPO in heptane, thorium is extracted into the organic phase, while americium and curium remain in the aqueous phase. The now purified thorium is finally back-extracted using 0.6 M H₂SO₄.

TBP in a range of organic solvents is also used frequently to extract thorium, together with uranium, neptunium and plutonium, from nitrate solutions. Following back-extraction of thorium is achieved by contacting the organic phase with an HCl solution. Alternatively, thorium can be complexed with EDTA before extraction with TBP, leaving thorium in the aqueous phase. HDEHP in toluene is also effective in extracting thorium from nitric, hydrochloric and perchloric acid solutions, as is TTA in benzene or toluene. Extraction at pH 1–2 from the latter gives an efficient separation of thorium from aluminum and uranium, as well as from the alkaline and rare earths. Separation of the extracted actinides from one another can be achieved by selective stripping from the organic phase with the appropriate mineral acid and molarity, and/or adjustment of oxidation state.

4.2.2 Separation of Uranium by Solvent Extraction

Solvent extraction from acid solutions into organic acids, ketones, ethers, esters, alcohols and organophosphorus compounds has been used extensively to separate uranium from other actinides and from a wide range of other elements. Extraction of uranium from a nitric medium (3–6 M) into TBP is particularly useful, as it allows separation of this element from iron, which is problematic by
from an 8 M HCl medium.\(^{60,111}\) After the addition of a few drops of 30% H\(_2\)O\(_2\), uranium, together with plutonium and neptunium, are extracted into the organic phase, leaving thorium and trivalent actinides in the aqueous phase. Plutonium, neptunium and uranium are then sequentially stripped from the organic phase with 0.05 M NH\(_4\)I–8 M HCl, 0.02 M HF–4 M HCl and 0.1 HCl, respectively.

TTA is a suitable complexing agent for uranium, forming a complex which can be extracted from aqueous solutions at pH 3 or higher using benzene as solvent.\(^{76}\) TOPO in cyclohexane or carbon tetrachloride has also been used for the extraction of uranium from a nitric medium and for the separation of this element from iron.

### 4.2.3 Separation of Neptunium by Solvent Extraction

Separation of neptunium from other actinides by solvent extraction can be achieved using a TOA–xylene (1 : 10 by volume) solution as extractant.\(^{94}\) In this method, HI is used to reduce neptunium to the tetravalent state in 10 M HCl medium under heat (70–80 °C). After cooling, neptunium is extracted into TOA–xylene medium, while thorium, americium and plutonium (converted to the trivalent state by HI) remain in the aqueous phase. The organic phase, containing neptunium and uranium, is washed with 10 M HCl and neptunium is back-extracted with 0.1 M HF–1 M HCl.

A similar procedure, based on the extraction of neptunium, plutonium and uranium into TIOA–xylene, followed by selective stripping of these elements, has already been discussed (section 4.2.2). An alternative approach, employing the TIOA–xylene combination as a first purification step prior to anion exchange, has recently been reported by Chen et al.\(^{92}\) Here, following successive coprecipitation steps (see section 3.4.3) with Fe\(^{3+}\) and K\(_2\)S\(_2\)O\(_5\), neptunium is extracted from a 9 M HCl medium, leaving plutonium in the aqueous phase. Neptunium is then back-extracted with 2 M HCl and a few drops of NaCl, co-precipitated as Fe(OH)\(_2\)–Np(OH)\(_4\), and dissolved in 12 M HCl prior to purification by anion exchange.

Sumiya et al.\(^{112}\) used solvent extraction with TTA–xylene to purify neptunium following anion exchange from an acetic medium, while Rameback and Skalberg\(^{113}\) reported an effective method to separate transuranics from large amounts of uranium using HDEHP. In Rameback and Skalberg’s procedure, uranium, neptunium, plutonium, americium and curium are extracted into HDEHP from a nitric medium. After the elimination of americium and curium with a 5 M HNO\(_3\) wash, neptunium is back-extracted with 1 M HNO\(_3\) containing hydroxy-lamine hydronitrate, leaving plutonium in the organic phase. Plutonium, if required, can be recovered by back-extraction with 3 M HCl containing Ti(III). This method has the advantage of completely eliminating uranium from the neptunium assay, and has been applied successfully to the determination of \(^{237}\)Np in samples of spent nuclear fuel by ICPMS.\(^{113}\)

### 4.2.4 Separation of Plutonium by Solvent Extraction

Solvent extraction of plutonium is most often carried out from a nitric medium, since the partition coefficients are generally higher than in a hydrochloric medium. Plutonium separation can be accomplished with a number of complexing agents, mainly organophosphorus compounds, amines and several chelating agents.

Among the organophosphorus compounds, HDEHP has gained widespread use and popularity in the separation of actinides. In a solvent extraction procedure introduced by Murray and Statham\(^{104}\) and designed to separate plutonium, americium and curium from environmental samples of seawater, sediment and marine biota, plutonium is efficiently extracted from an 8 M HNO\(_3\) medium into a 0.45 M solution of HDEHP in \(n\)-heptane, leaving trivalent americium and curium in the aqueous phase. The organic phase, containing the plutonium, is washed with several portions of 9 M HCl to remove thorium and much of the iron, prior to the back-extraction of plutonium using a freshly prepared solution of 8 M HCl–0.1 M NH\(_4\)I. In another scheme (for the separation of transuranium nuclides from large amounts of uranium), neptunium, plutonium, americium, curium and uranium are all extracted from HNO\(_3\) medium into HDEHP, after which the transuranium nuclides are back-extracted sequentially.\(^{113}\) Americium and curium are back-extracted with 5 M HNO\(_3\), neptunium with 1 M HNO\(_3\) containing hydroxylamine hydronitrate and, finally, plutonium with 3 M HCl containing Ti(III). In yet another separation scheme, actinides and lanthanides are extracted from an HClO\(_4\) medium into HDEHP.\(^{84,110}\) Trivalent actinides and lanthanides are stripped from the organic phase with 8 M HNO\(_3\), before plutonium is back-extracted with a 4 M HNO\(_3\) solution after reduction to the trivalent state with 2,5-di-tert-butylhydroquinone.

The most useful amines are tertiary amines such as TLA, TOA, TIOA and Aliquat-336. Singh et al.\(^{79,114}\) used TLA as an extractant for the separation of uranium, thorium and plutonium from environmental...
and biological samples. In this method, uranium and plutonium are extracted from 10 M HCl into a 20% TLA solution in xylene, leaving thorium in the aqueous phase. Plutonium is back-extracted by reduction to Pu(III) using a 0.05 M NH₄I solution in 8 M HCl, leaving uranium in the organic phase. Alternatively, plutonium in the tetravalent state can be extracted with 25% TLA in xylene from a 3 M HNO₃ medium.\(^{170}\) The organic phase must be washed twice with 10 M HCl to remove traces of thorium and then with 8 M HNO₃ to remove iron and uranium, before plutonium is stripped from the organic phase using 2 M H₂SO₄.

Hashimoto et al.\(^{115}\) used TOA in xylene to separate trace amounts of plutonium from macro amounts of uranium in 8 M HNO₃ solution. Butler\(^{111}\) developed a technique for the separation of plutonium, neptunium and uranium using TIOA. Chloride complexes of the three elements are extracted from an 8 M HCl medium into a 10% TIOA solution in xylene after the addition of a few drops of 30% H₂O₂ to adjust plutonium to the tetravalent state. Because thorium is unable to form anionic chloride complexes, it remains in the aqueous phase. Plutonium is stripped from the organic phase by reduction to Pu(III) using a warm, freshly made solution of 8 M HCl–0.05 M NH₄I, leaving neptunium and uranium in the organic phase.

Fisenne and Perry\(^{116}\) used Aliquat-336 for the separation of plutonium from biological samples. Here, tetravalent plutonium is extracted from 8.5 M HNO₃ into a 30% Aliquat-336 solution in toluene. Uranium and thorium are then eliminated by washing with HNO₃ and HCl, and plutonium back-extracted with 1 M HCl–0.01 M HF.

Of the many chelating agents which form extractable complexes with plutonium, TTA in benzene, xylene or carbon tetrachloride is the most often used. Plutonium(IV) is most efficiently extracted with this agent from nitric, hydrochloric or perchloric medium. The maximum extraction of plutonium with 0.1 M TTA in benzene takes place in the acidity range 0.5–1.0 M. Many ions accompany the extraction, including Zr(IV), Hf(IV), Ce(IV), Sn(IV), Th(IV), U(VI), Np(IV), Nb(V) and Fe(III).\(^{117,118}\) However, by adjusting the acidity of the solution it is possible to separate Pu(IV) from a number of other elements. For example, Bunzl and Kracke\(^{77}\) used TTA as extractant in the preparation of plutonium in biological samples. In this method, plutonium is extracted from 1 M HNO₃ into 5% TTA in benzene and back-extracted with 8 M HCl.

4.2.5 Separation of Americium and Curium by Solvent Extraction

Separation of americium and curium by solvent extraction is usually performed from an acidic medium using an organic phosphoric acid derivative as complexing agent. As noted above, Murray and Statham\(^{114}\) used HDEHP to separate plutonium, americium and curium from environmental samples. In this method, the lack of extractability of trivalent transplutonium elements from a strongly acidic solution (8 M HNO₃) in HDEHP is first used to separate americium and curium from other readily extractable elements (e.g. plutonium and uranium). The americium and curium are further purified from other interfering nuclides by extraction into HDEHP from an HNO₃ medium adjusted to pH 2, followed by repeated washes with 0.075 M HCl and back-extraction with 9 M HCl. Other schemes using organophosphorus reagents include the extraction of transuranium elements into HDEHP from a perchloric medium, with separation of americium and curium from plutonium and thorium by back-extraction into HNO₃,\(^{84,110}\) and separation of americium and curium from thorium in an 8 M HCl medium using TOPO.\(^{60}\) Bifunctional organophosphates such as DDCP possess a much greater extractability towards trivalent americium and curium, and have also been employed in numerous separation schemes in order to remove major interfering elements such as calcium, lead and radium.\(^{38,41,59,101}\)

A number of extraction methods for the purification of americium make use of the more unusual oxidation states of this element, that is Am(V) or Am(VI). However, the conversion and stability of americium to these higher oxidation states is difficult and their application to large numbers of environmental samples is unrealistic. A detailed review of methods for the preparation of americium in an oxidized form and its extraction in numerous media can be found in Schulz.\(^{119}\)

4.3 Example of a Scheme for the Separation and Purification of Actinide Nuclides

An example of a successful scheme combining anion exchange and solvent extraction for the separation and purification of actinides in environmental samples is described in detail in this subsection. The complete scheme is summarized in Figures 2–4, inclusive. In brief, anion exchange from an 8 M HNO₃ medium\(^{35}\) is first used to separate and purify thorium, plutonium and neptunium. The raffinate from this step is converted to 9 M HCl medium and passed through a second anion exchange column in order to separate and purify uranium, and eliminate iron.\(^{60}\) The raffinate from this second column is, in turn, converted to HNO₃–methanol medium and passed through a third anion exchange column in order to purify americium and curium.\(^{56}\) If further purification of the separated actinides is required, this can be achieved by, for example, solvent extraction into TIOA–xylene\(^{111}\) or HDEHP–heptane.\(^{104}\)
4.3.1 Detailed Method

Following appropriate preconcentration steps (see section 3), the sample is conditioned in 8 M HNO₃ medium; this is the starting point of the separation scheme shown in Figure 2. Upon conversion of plutonium to the tetravalent state by the addition of NaNO₂, the sample is passed through an anion exchange resin (e.g. Dowex 1X8, 80 mm by 7 mm diameter), previously conditioned in 8 M HNO₃, at a flow rate of 1–2 mL min⁻¹. Following the sample, an additional 50 mL of 8 M HNO₃ is passed to purge the dead volume of the column. Raffinate and wash are retained for subsequent uranium, americium and curium analysis. Thorium, plutonium and neptunium are then sequentially stripped from the column using 75 mL of 12 M HCl, 50 mL of warm 12 M HCl–0.1 M NH₄I, and 50 mL of 3 M HCl–0.02 M HF, respectively.

If further purification of plutonium is indicated, some additional steps are required. Firstly, the plutonium eluate is evaporated to dryness, the residue dissolved in HNO₃ (to eliminate iodine) and HCl, evaporated to dryness again, and finally redissolved in 30 mL of 8 M HCl after conversion to the chloride form by successive additions of 12 M HCl. A few drops of H₂O₂ are added to convert plutonium to the tetravalent state, after which the solution is shaken vigorously for 5 min with TIOA–xylene extractant, previously equilibrated with fresh 8 M HCl. Plutonium and any traces of neptunium and uranium are extracted into the organic phase. The aqueous phase, containing small traces of iron and thorium, is discarded. Plutonium is then back-extracted from the organic phase using a freshly made (and warm) solution of 8 M HCl–0.05 M NH₄I.

A similar approach can be used to further purify neptunium. In this case, neptunium is extracted into TIOA–xylene from an 8 M HCl medium together with any traces of plutonium and thorium. Plutonium is eliminated first by stripping with an 8 M HCl–0.05 M NH₄I solution as above, and neptunium subsequently recovered by back-extraction into a 4 M HCl–0.05 M HF solution.

Purification of uranium from americium and curium is carried out by anion exchange in a 9 M HCl medium (Figure 3) as follows. The combined 8 M HNO₃ raffinate and wash from the first exchange column is evaporated
to dryness, redissolved in 100 mL of 9 M HCl and passed through an anion exchange column (e.g. Dowex 1X8, 80 mm by 7 mm diameter) previously equilibrated in this medium. A 100-mL wash of 0.1 M HCl–0.1 M NH₄SCN–86% methanol is then passed through the column to elute lanthanides as well as any traces of uranium. Americium and curium are finally eluted from the column using 50 mL of 1.5 M HCl–86% methanol.

Further purification of americium and curium can be effected by an additional solvent extraction step. By converting the eluate to an 8 M HNO₃ medium and shaking with 0.45 M HDEHP in n-heptane, residual traces of uranium, plutonium and thorium are extracted into the organic phase, while americium and curium are left in the aqueous phase.

In summary, the scheme described above permits the simultaneous determination of thorium, uranium, neptunium, plutonium, americium and curium, and has proved very reliable for the assay of actinides in a wide range of environmental matrices, for example, seawater, soil, sediment and biological materials. Chemical recoveries in the range 70–90% are routinely achieved with this method.

4.4 Extraction Chromatography

With the development of new, highly selective resins in recent years, the technique of extraction chromatography, which combines the selectivity of solvent extraction with the speed and convenience of chromatography, has been used increasingly in the low-level assay of actinides.\(^{120,121}\)

In extraction chromatography, an organic extractant (e.g. TOPO, HDEHP, TBP, Aliquat-336) is supported on an inert porous resin (e.g. microporous polyethylene) by adsorption or by the capillary effect. The coated resin is transferred to a column and preconditioned in the usual manner. As the sample is passed, the actinide(s) of interest is selectively extracted onto the resin. After elimination of impurities (as in ion-exchange chromatography), actinides are eluted (back-extracted) using appropriate elutants (extractants).

Resins using the quaternary amine Aliquat-336 as extractant (e.g. Eichrom’s TEVA resin) have proved to be very effective for the separation of tetravalent actinides as anionic complexes, and for the separation of most actinides from interfering lanthanides.\(^{120,122,123}\)

Resins using dianylamylphosphonate as extractant (e.g. Eichrom’s UTEVA resin) have shown great selectivity for uranium and tetravalent actinides, extracted as neutral complexes,\(^ {122,124–128}\) while resins based on the synergistic effect of a combined octylphenyl-N,N-di-isobutyl carbamoylphosphate oxide/TBP extractant...
(Eichrom’s TRU resin) have proved highly specific for the extraction of transuranium nuclides from a nitric medium.\(^\text{17,122,129–131}\)

Despite the higher cost of commercial extraction chromatography resins compared to conventional ion exchange resins and the implications in quality assurance/quality control terms which the implementation of new protocols in accredited laboratories represent, the reduction in analysis time, reagent costs and resulting chemical wastes can offer attractive advantages over more traditional techniques.

### 5 CHEMICAL SPECIATION ANALYSIS

It has long been recognized that the mobility and bioavailability of any element in the environment, particularly the aquatic, is strongly influenced by its physical and chemical form. Of no element is this more true than for plutonium, which can exist in solution in at least four different oxidation states simultaneously. These states include plutonium(III), plutonium(IV), plutonium(V) and plutonium(VI), of which plutonium(IV) and plutonium(V) predominate in oxygenated waters as the reduced (hydrolized) \(\text{Pu(OH)}_n\) and the oxidized \(\text{PuO}_2^+\) forms, respectively.\(^\text{132–134}\) While plutonium in reduced form is highly particle-reactive, being quickly adsorbed by suspended particles, sediments and natural colloids, plutonium in oxidized form is much more soluble and can be transported over great distances within the solution phase. Clearly, accurate data on the speciation of plutonium or, for that matter, any other element exhibiting multivalent behavior, are essential when there is a need to model its transfer within the aquatic environment and predict its likely impact on man.

Field studies have confirmed that, in the absence of complexing agents, oxidized forms of plutonium predominate in the dissolved (<0.45 μm) phase in natural waters.\(^\text{135–138}\) The presence of significant levels of complexing agents (such as dissolved organic carbon) results in a redistribution in the partitioning of plutonium between the dissolved and particulate phases, and in the proportions of the various chemical species present in the dissolved phase. According to theoretical speciation calculations, Pu(III) should predominate in the dissolved phase under reducing conditions.\(^\text{139,140}\) Indeed, colloidal organic carbon at concentrations commonly encountered in natural waters (1–20 mg L\(^{-1}\)) has been shown to strongly interact with Pu(III,IV) species and inhibit their sorption onto suspended particles.\(^\text{141,142}\) Speciation studies of plutonium adsorbed onto suspended particulate and sediment have shown plutonium to be present almost entirely in reduced chemical form.\(^\text{135,138}\)

In the case of americium and curium, it is well established that the solution chemistry of both elements is dominated by the trivalent Am(III) and Cm(III) forms. Indeed, the dominance of highly insoluble forms of americium and curium such as Am(ΟH)\(_n\)\(^{2+}\) and Cm(ΟH)\(_n\)\(^{2+}\) in alkaline solutions is predictable.\(^\text{143}\) Measurements on the chemical speciation of americium in filtered water from the north-eastern Irish Sea appear to confirm that americium is present almost exclusively as Am(III).\(^\text{144}\) Accordingly, a much greater proportion of americium (and curium) than plutonium can be expected to be in a highly insoluble, hydrolyzed form, leading to a stronger affinity for suspended particulate matter, colloids and sediments.

In solution, thorium exists only in the tetravalent state, characterized by a strong sedimentary affinity. In contrast, under normal oxidizing conditions, hexavalent (UO\(_2\)\(^{2+}\)) is the stable oxidation state of uranium and presents in the form of soluble carbonate complexes.\(^\text{145}\) Under moderately strong reducing conditions, however, uranium is reduced to the tetravalent state. The same is true for neptunium, which in normal oxidizing conditions exists in the pentavalent form as (NpO\(_2\))\(^+\), but can be reduced to Np\(^{4+}\) under reducing conditions.\(^\text{4}\)

The determination of the oxidation state distribution of actinides in aqueous media is based on the use of multiple yield monitors (ideally, one for each of the oxidation states present) throughout the entire extraction state separation procedure. To illustrate, we shall consider the case of plutonium in a natural water system in some detail. For many purposes, “reduced” plutonium can be regarded as the sum of the plutonium in oxidation states (III) and (IV), and “oxidized” plutonium as the sum in oxidation states (V) and (VI). This assumption is based on the similarity in behavior between plutonium(III) and (IV) species and reduced elements such as La(III) and Th(IV), and between plutonium(V) and (VI) species and oxidized elements such as Np(V) and U(VI).\(^\text{133}\) These similarities constitute the basis of a technique for the sequential separation of the lower (II,IV) and higher (V,VI) oxidation states of plutonium in natural waters by coprecipitation with rare earth fluorides.\(^\text{135}\) which is described in some detail below.

To separate the reduced and oxidized species of plutonium, it is necessary to use two plutonium yield monitors in pure, but different, chemical forms. These chemical forms should be identical to those of the species under examination. This allows corrections to be made for the (usually) small carry-overs that invariably take place between the reduced and oxidized species in the course of analysis. The recommended chemical forms are Pu\(^{4+}\) for the reduced species and either PuO\(_2\)\(^{2+}\) or PuO\(_2\)\(^2+\) for the oxidized species. A full description of the methods use to prepare plutonium tracers in these oxidation states.
can be found elsewhere; here, a brief outline only will be given.

Essentially, a purified solution of, for example, $^{242}$Pu(IV), is prepared by passing $^{242}$Pu in 8 M HNO$_3$ through an anion exchange column (e.g. AG 1X8, NO$_3^-$ form). Plutonium is then eluted with an appropriate volume of 0.1 M HNO$_3$ and the eluate combined immediately with an equal volume of 16 M HNO$_3$ to give $^{242}$Pu(IV) in approximately 8 M HNO$_3$.

Preparation of the oxidized tracer requires the use of an electrolytic cell (Figure 5). A solution of 2–3 mL of 0.8 M HNO$_3$, containing a different plutonium isotope to that of the reduced tracer (e.g. $^{236}$Pu or $^{244}$Pu), is placed in the anodic compartment of the cell, whilst the cathodic compartment is filled to the same level with pure 0.8 M HNO$_3$. Direct current is passed through the cell at 3.5 V for about 16 h, leaving some two-thirds of the activity added at the outset in the anodic compartment as oxidized Pu(VI).

Solutions of pentavalent plutonium can be prepared by extracting Pu(VI) from a dilute acetate solution with TTA, irradiating the organic phase with fluorescent light in order to induce the photo-reduction of plutonium(VI) to plutonium(V), and back-extracting Pu(V) with 0.1 M sodium acetate. It is also possible to prepare Pu(V) directly by electrolytic oxidation in 1 M HCl medium.

Returning to the determination of the oxidation state distribution of plutonium in, for example, natural waters, the first action is to microfilter the sample, preferably in situ. Following this, and without delay, two isotopic monitors in different oxidation states, e.g. $^{242}$Pu(IV) and $^{236}$Pu(VI), are added to the sample which is made 0.8 M in HNO$_3$, 0.25 M in H$_2$SO$_4$, 0.0005 M in K$_2$Cr$_2$O$_7$ and 0.0007 M in Nd. The addition of a holding oxidant (K$_2$Cr$_2$O$_7$) prevents the reduction of the higher oxidation states by reducing agents used in the next step, in which neodymium, added as Nd(NO$_3$)$_3$, is precipitated as NdF$_3$ having made the sample 0.25 M in HF. The precipitate, containing the reduced plutonium species only, is collected by filtration and retained for analysis. The oxidized species, which have remained in solution, are subsequently reduced by the addition of ferrous ammonium sulfate and coprecipitated with NdF$_3$ by again making the sample 0.0007 M in Nd. This precipitate is also collected by filtration and retained for analysis of the oxidized fraction. Excellent separation between the oxidation state groups is normally achieved, with carry-overs, typically, being a few percent or less. Although small, these carry-overs should be corrected for; this is easily done, as they are readily quantifiable.

It should be stressed that the sequential coprecipitation method described above cannot distinguish plutonium(III) from plutonium(IV), nor plutonium(V) from plutonium(VI), due to the oxidizing effect of K$_2$Cr$_2$O$_7$. Although calculations based on thermodynamic considerations suggest that PuO$_2^{+}$ is the predominant oxidized species (at least in seawater), confirmation of this prediction is not possible using the above technique alone. However, in principle, it is possible to determine the percentage of plutonium(VI) in the oxidized fraction if a separate experiment is performed, using an identical sample of water, in which plutonium in oxidation states (III), (IV) and (V) is removed by the addition of excess calcium carbonate (~20 mg of CaCO$_3$ per liter of sample is usually sufficient). Since the scavenging of plutonium(V) by calcium carbonate is not 100% efficient, the experiment should also be carried out with dual monitors, one to label the Pu(V) fraction and the other Pu(VI). It is assumed that the removal of Pu(III) and Pu(IV) by CaCO$_3$ is quantitative. Alternatively, Pu(VI) can be scavenged with Pu(III) and Pu(IV) using hydrated silicon dioxide.

Upon return to the laboratory, the filters containing the precipitate of each plutonium fraction are separately dissolved in concentrated HNO$_3$ in the presence of small quantities of boric acid (this facilitates the elimination of excess fluoride). Each solution is then diluted to an appropriate volume with distilled water and neutralized with ammonia to a pH of ~9. The resulting precipitates are separated by centrifugation and redissolved in 16 M HNO$_3$. After evaporation, the residues are finally redissolved in 8 M HNO$_3$, and 1 mL of saturated Al(NO$_3$)$_3$ solution in 8 M HNO$_3$ added to enhance the separation of plutonium from neodymium in the subsequent purification step (anion exchange as described in section 4.3).
6 SOURCE PREPARATION

6.1 Sources Suitable for Counting by $\alpha$-Spectrometry

Following radiochemical purification, the actinide of interest must be mounted on a suitable surface or substrate prior to $\alpha$-spectrometry. This is one of the most critical steps in the whole process, as the quality of the source is often the limiting factor in determining the quality of the observed spectrum. Ideally, a source of good quality should approximate closely to a near infinitely thin, massless, uniformly active deposit in order to minimize energy degradation caused by (1) energy-loss straggling, (2) variations in the path lengths of the emitted particles due to nonuniformity in the thickness of the source, and (3) local variations in the stopping power due to the inhomogeneous composition of multi-element sources.

Several techniques have been developed to prepare sources of spectrometric quality including vacuum sublimation, electrospraying, evaporation, direct or electrostatic precipitation and electrodeposition. Although the best sources are produced by vacuum sublimation, the low efficiency of this method (1–25% depending on the active source area and source uniformity required) has limited its use in the analysis of low activity environmental samples which demand near quantitative recovery. Instead, electrodeposition has been the method most commonly employed to obtain undegraded spectra with good deposition yields, providing rugged sources suitable for storage for long periods of time.

Electrodeposition of actinides from an aqueous solution involves the cathodic deposition of their hydrolysis products following the passage of a direct current through an appropriate electrolyte. Plating from a variety of different electrolyte media has been reported in the literature, though acidic solutions containing ammonium sulfate, ammonium chloride, ammonium chloride/ammonium oxalate mixtures or ammonium chloride/ammonium oxalate have become the most widely used. While a sulfate medium is reported to yield marginally higher recoveries, it has been suggested that better quality sources are produced with an ammonium chloride/ammonium oxalate medium. Further, plating from the latter requires somewhat shorter plating times and is not as critically dependent on pH. Accordingly, we have chosen to discuss electrodeposition from a chloride/oxalate medium here.

A typical electrolytic cell is depicted in Figure 6. It consists of a high quality, polypropylene sleeve (disposable), threaded into a stainless-steel support, which acts as both an electrical contact and a heat sink. A highly polished stainless-steel disk (20-mm diameter), mounted on this support, acts as the cathode. The anode is made of platinum and consists of a thin flat disc, 11 mm in diameter, held about 8 mm from the cathode by a platinum wire threaded through a PTFE lid shaped to facilitate the return of condensed vapor to the electrolyte.

Figure 6 Schematic of a typical electrodeposition cell.

Although the use of platinum as cathodic material has been reported to yield better quality sources, the high cost of this metal prevents its use in routine analysis, unless the discs are cleaned and reused. This is not advisable when undertaking trace level analyses. The better quality of platinum-supported sources as compared to stainless-steel is said to be due to the dissolution and subsequent replating of elemental constituents of the stainless-steel discs during electrodeposition. However, it has been reported that the use of a chloride–oxalate medium is not accompanied by any noticeable cathodic corrosion. Some workers have recommended the use of a rotating cathode for best results. However, the practice has not been widely adopted.

To prepare the source for $\alpha$-spectrometry, the purified solution containing the actinide of interest in, for example, nitrate medium is evaporated to dryness and the nitrate salts eliminated by the repeated addition and evaporation of small amounts of HCl. The residue is redissolved in a solution comprising 1 mL of 3 M HCl and 8 mL of 1 M ammonium chloride–0.01 M ammonium oxalate, together with a few drops of thymol blue pH indicator. The pH of the solution is adjusted to ~2.0 by the dropwise addition of a 50% (v/v) solution of NH$_4$OH (thymol blue indicator becomes salmon-pink in the pH range 2.0–2.3). This pH value is within the range found to yield maximum deposition. The solution is
transferred to the electrolytic cell and plating carried out by passing a direct current of 1.0 A through the cell for 45–60 min. One minute before switching off the current, the solution is neutralized by the addition of 1 mL of concentrated ammonia in order to prevent redissolution of the deposited actinide upon removal of the electric field. Once the cell is disconnected and the system disassembled, the electroplated disc is rinsed gently with distilled water and acetone, dried at room temperature and heated at 500 °C for 30 s in order to better fix plated actinide hydroxides by conversion to their more stable oxides and to volatilize any remaining traces of polonium.

6.2 Sources Suitable for Liquid Scintillation 
α-Spectrometry

Liquid scintillation α-spectrometry\(^\text{156}\) offers an attractive alternative to conventional α-spectrometry in cases where the total α-activity or the activities of energetically well-resolved actinides are to be assayed, in that it provides virtually 100% counting efficiency and eliminates the problem of self-absorption. Sources are prepared by incorporating the purified α-analyte nuclide(s) in a liquid scintillation cocktail, that is, an organic solvent (e.g. toluene, benzene, xylene) containing a fluor (e.g. POPOP, PPO) and, in many though not all cases, an energy transfer agent such as naphthalene.\(^\text{157}\) It is a fundamental requirement of this counting method that the analyte be distributed homogeneously within the cocktail. As the analyte is usually in aqueous form, sources can be prepared simply by mixing the analyte solution with an aqueous-accepting scintillation cocktail and shaking vigorously for a few seconds. Unfortunately, the introduction of an aqueous sample to an aqueous-accepting scintillator is not to be recommended if the lowest background, best (α-) energy resolution, and best separation of β-γ- pulses from α-pulses are desired, that is, if color quenching and chemical quenching are to be avoided. Instead, the use of an extractive scintillator (an aqueous-immiscible organic solution containing both the scintillator components and a liquid–liquid extraction reagent for transferring the analyte of interest to the cocktail) is now the method of choice in many laboratories, particularly when there is a requirement to discriminate between α- and β-emitting nuclides.\(^\text{156}\)

6.3 Sources Suitable for Mass Spectrometric Counting

Procedures for the preparation of sources suitable for counting by mass spectrometry are clearly dependent on the nature of the analyte phase (solid, liquid or gas) and on the type of spectrometry proposed, for example, ICPMS, thermal ionization mass spectrometry (TIMS) and AMS.

In the case of ICPMS, by far the most common method of sample introduction reported is that of pneumatic nebulization, in which a fine aerosol of analyte droplets is injected into the plasma.\(^\text{158}\) This method is, however, very inefficient and alternative techniques such as electrothermal volatilization (ETV) and laser ablation are increasingly being used.

ETV from a graphite rod or a refractory wire is a very convenient method of introducing small samples of a few microliters to the plasma. It produces a transient signal lasting a few seconds while the jet of vapor from the heated surface traverses the plasma.\(^\text{158}\) Laser ablation is employed for the direct analysis of solid samples. A single laser shot with an energy of approximately 0.5 J focused on the surface of the sample can ablate 50–100 µg of material in the form of vapor and condensed microparticulates.\(^\text{158}\)

In TIMS, the analyte is evaporated on to a rhenium or tungsten filament (with an appropriate salt to enhance the ionization process), prior to heating and measurement.\(^\text{76,158}\)

In AMS, the analyte is dispersed in an iron oxide matrix, produced by dissolving the analyte in HNO₃, adding iron nitrate, evaporating to dryness, and baking at 800 °C to convert the nitrate to oxide. The iron oxide matrix is then mixed with aluminum powder (which serves as both an electrical and a thermal conductor) and pressed firmly into a suitably designed sample holder.\(^\text{159,161}\)

7 RADIOMETRY

7.1 α-Spectrometry

α-Spectra from thin sources are nowadays measured with passivated (ion-) implanted planar silicon (PIPS) detectors. The PIPS detector is essentially a thin wafer of partial or totally depleted silicon formed by reverse biasing a p–n junction. In the depleted region of the junction, which constitutes the sensitive volume of the detector, α-particles lose most of their energy in electronic excitation and ionization, with the production of electron–hole pairs by electron transfer from the valence band to the conduction band of the crystal. These charge carriers are swept out to the edges of the depleted region by the applied electric field, generating an electronic pulse whose amplitude is directly proportional to the number of charge carriers collected.

Ideally, the amplitude of the pulse should be strictly proportional to the energy of the incident particle. In practice, however, a number of physical processes from which no charge is collected and the statistical nature of the processes involved in the generation of the signal give rise to a detector response with nonzero
variance, limiting the energy resolution of the system.\(^{162}\) Electronic energy loss straggling in the dead layer (i.e. layer at the surface of the detector through which \(\alpha\)-particles must pass before reaching the depleted volume), non-electronic losses in the depleted region, electron–hole pair statistics and electronic noise contribute to the width and asymmetric shape observed in the pulse height spectrum of monoenergetic \(\alpha\)-particles.\(^{149,163}\) Since no improvement in the intrinsic response of the detector to the incoming radiation can be achieved, a major goal in the design and operation of these detectors is to make the contributions to the peak width arising from energy losses in dead layers (in both detector and source) and electronic noise as small as possible.

Modern PIPS detectors approach the theoretical resolution limits of silicon detectors very closely, making them the preferred choice for most applications in high resolution \(\alpha\)-spectrometry. The planar process used in the fabrication of PIPS detectors combines passivation, photolithographic patterning and doping techniques to produce high quality radiation detectors with thin entrance windows and low electronic noise.

The window (face contact) of a PIPS detector consists of a very thin (<50 nm) heavily doped \(p^+\) layer, usually produced by low-energy implantation of boron ions into the silicon wafer. This implanted window is substantially thinner than the delicate metallic contacts of earlier silicon surface barrier detectors, which consisted of a thin evaporated layer of gold (\(\sim 80\) nm) or aluminum (\(\sim 200\) nm). It is also a more rugged and stable surface, which can be readily cleaned with mild solvents. The thinner window of the PIPS detector results in improved resolution, even at close source-to-detector spacings. This is important in environmental studies, where the activities involved are often very low and maximum efficiency with minimal loss of resolution is highly desirable.

The electronic noise of a semiconductor junction-type detector is basically determined by its reverse current and capacitance.\(^{164}\) The reverse current not only sets a limit for the detection of low-energy charged particles but also contributes to the degradation of the energy resolution. The reverse current is the sum of the diffusion current, surface leakage current and so-called bulk generation current. The passivation step, in which a silicon dioxide layer is created in the surface of the silicon wafer by thermal oxidation, suppresses the surface leakage current,\(^{165}\) reducing the reverse current of a modern \((450\) mm\(^2\)) PIPS detector to \(\sim 10\) nA.

PIPS detectors are available with active areas between 25 and 3000 mm\(^2\) and depletion depths between 100 and 700 \(\mu\)m. Since the electronic noise of the preamplifier increases with increasing capacitance,\(^{162}\) improved energy resolution can be achieved with detectors of smaller active area and greater depletion depth. This is, however, at the expense of detection efficiency, which diminishes with diminishing active area, and of reverse current, which increases with the increasingly large voltages required to extend the depth of the depleted region.\(^{166}\)

### 7.1.1 \(\alpha\)-Spectrometric Set-up

The excellent operational characteristics of PIPS detectors do not, of themselves, guarantee the best possible resolution. The long counting times needed to record the spectra of low activity sources with good statistics also require reliable, drift-free, high stability electronics. An example of a multiple detector system, specially designed for low-level analysis, is depicted in Figure 7. The system provides each PIPS detector with vacuum, bias supply and preamplifier/amplifier, routing the output signal from the latter into a dedicated segment of a multichannel analyzer (MCA) via an analog-to-digital converter (ADC). The vacuum in each chamber is maintained at \(\sim 0.7\) Pa by means of a rotary vacuum pump. The bias voltage applied to each detector is set to the value recommended by the manufacturer (typically 40–60 V) and interlocked to a vacuum gauge to ensure that bias is not supplied under poor vacuum conditions.

Sources are normally mounted horizontally in source holders fabricated from low-background materials. A reverse bias of 10 V DC is applied to each source/holder.

![Figure 7](image-url)

**Figure 7** A typical \(\alpha\) spectrometric set-up.
which, together with the small amount of air intentionally left in the counting chamber (equivalent to \(\sim 16 \text{ mg cm}^{-2}\)), helps to prevent detector contamination by so-called alpha-recoil (i.e. contamination due to recoiling fragments which become embedded in the detector following alpha-decay). For routine low-level actinide analysis with 450-mm\(^2\) detectors, a typical source-to-detector spacing is \(\sim 5 \text{ mm}\). At this separation, an energy resolution (full width at half-maximum) of 18–20 keV is readily achievable, provided that the source is of good quality. For analyses requiring the highest resolution, it is customary to use a detector of smaller active area (say 100 mm\(^2\)) and to increase the source-to-detector spacing to \(\sim 10–15 \text{ mm}\) in order to improve collimation. In this configuration, energy resolutions of 10–12 keV are attainable with high quality electroplated sources.

In the arrangement shown in Figure 7, the pulses from each detector are processed by a preamplifier/amplifier module incorporating a low-noise, charge-sensitive preamplifier with a diode-protected field effect transistor (FET) front end, and a linear shaping amplifier which provides the necessary level of signal conditioning for high-resolution spectrometry. The output from each amplifier is fed to a mixer/router, digitized by an ADC and routed to one of the memory segments (typically 512 channels each) of a personal computer-based MCA.

### 7.1.2 \(\alpha\)-Spectra

If the radiochemical purification and source preparation protocols described above are successfully implemented, the resulting spectra are usually quite simple, consisting of a small number of well defined peaks on a small, discrete background. Typical \(\alpha\)-spectra of thorium, uranium, plutonium and americium are shown in Figures 8–11, inclusive. In each spectrum, one of the “peaks” (actually an unresolved or partially resolved doublet or multiplet) corresponds to the tracer nuclide added to monitor the radiochemical yield. In the absence of spectral interferences, the analysis reduces to the integration of the number of counts under each “peak” and the subtraction of the corresponding background. The activity of the analyte nuclide is then obtained simply from the ratio of its peak area to that of the tracer peak multiplied by the known activity of the tracer (in becquerels).

### 7.1.3 Background Measurements

The background of a PIPS detector is generally very low, of the order of \(10^{-5} - 10^{-6} \text{ s}^{-1}\) for a region of interest of say 100 keV. With use, however, the background tends to increase by nuclide evaporation or recoil contamination. Since background subtraction may be of significance,
especially at the low activities often encountered in environmental samples, periodic background measurements must be carried out to check for any contamination that may have arisen (e.g. in the course of analysis or laboratory operations) and ensure accurate background corrections.

7.1.4 Spectral Interferences

Spectral interferences are considered to occur when the α-emissions from different nuclei overlap in energy. This may be because the various peaks have similar energies and cannot readily be resolved from one another, or because of the tailing of well-resolved peaks to lower energies when counting “thick” (i.e. poor quality) sources. Spectral conflicts increase the uncertainty of the analysis to the point of making it impossible for spectra (and, by extension, sources) affected by severe interferences. In extreme cases, the best cure is the careful repurification of the source, followed by replating and recounting.

In some cases, the small energy separation between the α-emissions of two or more isotopes of a particular element results in the creation of unresolved (or only partially resolved) multiplets. This type of overlap is unavoidable and is usually dealt with by quoting the summed activities of the composite peak (e.g. $^{239+240}$Pu, $^{243+244}$Cm).

More difficult to unravel are the overlaps that arise from the incomplete removal of certain impurity nuclides, e.g. members of the natural radioactive decay series. For example, in the case of thorium spectra, the rapid ingrowth of a $^{224}$Ra peak (intensity 5.1%) under the $^{228}$Th peak should be taken into account by measuring the main $^{224}$Ra peak (intensity 94.5%) and estimating the contribution from $^{224}$Ra in the $^{228}$Th window on the basis of the relative intensities of the two $^{224}$Ra peaks. Moreover, when using a mixed $^{232}$U/$^{228}$Th tracer, care must also be taken to account for the presence of indigenous $^{228}$Th, which originates from the $^{232}$Th → $^{228}$Ra → $^{228}$Th natural decay chain. One way to do this is to assume that the $^{228}$Th and $^{232}$Th are in secular equilibrium. This is not always the case, however, and the analysis of an unspiked replicate sample to establish the actual $^{228}$Th/$^{232}$Th activity ratio becomes imperative, unless one is certain of the equilibrium assumption. The problem does not arise when $^{229}$Th is used as yield monitor.

The analysis of uranium spectra using $^{232}$U as monitor is straightforward, in that the $^{238}$U, $^{235}$U, $^{234}$U and $^{232}$U peaks are usually well resolved from one another. Care must be taken, however, to count the sources soon after sample purification, as short-lived daughter nuclides ingrow quickly, yielding peaks, some of which cannot be resolved from the peaks of interest.

In the case of transuranium spectra, the main interferences arise from the presence of (1) a $^{234}$U peak in the $^{242}$Pu window, (2) $^{210}$Po in the $^{243}$Am window, (3) $^{228}$Th in the $^{238}$Pu or $^{241}$Am window (the energies being similar), (4) $^{224}$Ra in the $^{243,244}$Cm window, and (5) $^{212}$Bi in the $^{242}$Cm window.

When measuring plutonium in samples of marine origin, the contribution of $^{234}$U to the $^{242}$Pu peak can be corrected for by using the well-known ratio of $^{234}$U to $^{238}$U in this environment, namely 1.14 ± 0.01, to determine the number of counts in the $^{242}$Pu window due to $^{234}$U. For samples of other origin, sources must be stripped and repurified until essentially no $^{238}$U appears in the spectrum.

Th-228 interference in the $^{238}$Pu or $^{241}$Am window is corrected for by assuming secular equilibrium between $^{228}$Th and its daughter nuclides $^{224}$Ra, $^{220}$Rn, $^{216}$Po and $^{212}$Bi after the appropriate ingrowth period (i.e. at least 2 weeks post-electrodeposition). The same correction can be applied to the $^{224}$Ra interference in the $^{243,244}$Cm window and to the $^{212}$Bi interference in the $^{242}$Cm window.

The contribution to the peaks of interest from possible trace impurities in the yield monitors and chemical reagents used should also be taken into account by the periodic analysis of appropriate reagent blanks. Finally, when operating outside the normal laboratory environment, for example, when in the field or aboard a research vessel, the analysis of field blanks should be an essential component of the overall analytical program.

7.1.5 Calculation of Activity

Once the area under each peak is corrected for background, field/reagent blank and spectral interference, the mass activity (or activity concentration) of the analyte
nuclide can be determined using Equation (5):
\[ C = \frac{N_s A_T}{N_T m} \]  
where \( C \) is the mass activity (or activity concentration) in the sample (Bq unit\(^{-1}\)), \( N_s \) is the net number of counts in the analyte peak, \( A_T \) is the activity of the yield monitor added to the sample (Bq), \( N_T \) is the net number of counts in the yield monitor peak, and \( m \) is the size of the sample in appropriate units (i.e. kg, m\(^{-3}\)). The chemical recovery of the sample can also be determined using Equation (6):
\[ R(\%) = \frac{N_T 100}{A_T \Omega} \]  
where \( t \) is the counting interval (s), and \( \Omega \) is the fractional solid angle. The uncertainty associated with the calculated activity is easily determined using quadratic error propagation theory.

7.1.6 Limits of Detection and Quantitation

The limit of detection (LOD) is the lowest concentration of an analyte that the analytical process can reliably detect. The LOD in most instrumental methods is based on the relationship between the gross analyte signal, \( S_x \), the field blank, \( S_b \), and the variability in the field blank, \( \sigma \). The LOD has been variously defined by the extent to which the gross signal exceeds \( S_b \):
\[ S_x - S_b \geq K_d \sigma \]  
where \( K_d \) is a constant factor. It is recommended that detection should be based on a minimal value for \( K_d \) of 3, so that the LOD is located at 3\( \sigma \) above the gross blank signal, \( S_b \). This is illustrated in Figure 12, which depicts the region of detection of analyte in the gross signal as \( S_t \geq S_b + 3\sigma \), and similarly for the net signal as \( S_x \geq S_d \).

Thus, in \( \alpha \)-spectrometry, the lower limit to detection, expressed in concentration units, would then be obtained from the net signal using Equation (7)
\[ \text{LOD(Bq unit}^{-1}\text{)} = \frac{S_d}{\Omega m t R} = \frac{3\sigma}{\Omega m t R} \]  
where, again, \( \Omega \) is the fractional solid angle, \( m \) is the sample size (unit), \( t \) is the counting interval (in seconds) and \( R \) is the fractional radiochemical yield or recovery.

While a value of \( K_d = 3 \) is considered minimal, higher values may be required since this value implies definite risks of 7% for false positive (concluding that the analyte is present when it is absent) and false negative (the reverse) decisions. This is recognition that the numerical or statistical significance of the apparent analyte concentration increases as the analytical signal increases above the LOD. In other words, there is need for a second, more stringent definition, namely a limit of quantitation (LOQ), located above the measured average field blank, \( S_b \), by the following definition:
\[ S_t - S_b \geq K_q \sigma \]

In this case it is recommended that the minimum value for \( K_q \) be 10. The region of quantitation is also depicted in Figure 12. Combined, the two definitions define the region of detection \( S_q > S_t > S_d \) and the region of quantitation \( S_t \geq S_q \).

In the context of low-level assay by \( \alpha \)-spectrometry, a representative LOQ (calculated on the basis of an average field blank count rate of \( 5 \times 10^{-6} \) s\(^{-1}\), a fractional solid angle of 0.28, a recording time of \( 2 \times 10^6 \) s (about 3 weeks), and a radiochemical yield of 80%) would be \(~50\mu\text{Bq}\). For a water sample of say 100 L, this is equivalent to an activity concentrations of \(~0.5 \text{ mBq m}^{-3}\), while for a solid sample of 10 g it represents \(~5 \text{ mBq kg}^{-1}\).

7.2 Liquid Scintillation \( \alpha \)-Spectrometry

In liquid scintillation spectrometry, as explained above, the sample is placed in direct contact with a liquid scintillation cocktail, normally composed of one or more fluorescent solutes in an organic solvent. The energy of the \( \alpha \)- or \( \beta \)-particles emitted by the source is lost in excitation and ionization of solvent molecules. Activated solvent molecules subsequently transfer their excess energy to dissolved organic scintillator molecules, which are brought to an excited state. When these scintillator molecules return to their natural or ground state, energy is lost in the form of light and heat. The intensity of the light produced in the scintillation cocktail is directly proportional to the energy of the particle. The flash of light is simultaneously detected by two photomultiplier tubes operating in coincidence mode, giving rise to an electronic pulse whose amplitude is

---

Figure 12: Schematic of the minimal criteria recommended by the American Chemical Society’s Committee on Environmental Improvement. (Source: ACS, 1980)
linearly related to the energy of the particle. A simple block diagram of a modern liquid scintillation counter is shown in Figure 13. The purpose of the coincidence unit is to reduce background caused by photomultiplier tube noise. The summation circuit adds the signals from both photomultipliers, optimizing the signal-to-noise ratio for optimum detection.

Since the sample is in direct contact with the scintillation cocktail, it can influence the intensity of the light produced in the scintillation process. This phenomenon of reduced light intensity is termed quenching and has to be taken into account, especially when counting low-energy $\beta$-emitters. Traditionally, quenching is classified into two broad categories, namely chemical quenching and color quenching.$^{156,168}$ Chemical quenching occurs when excited solvent molecules fail to transfer energy to scintillator molecules (the fluor) or instead transfer their energy to nonlight-producing molecules, whereas color quenching occurs when the emitted light is absorbed or attenuated before it can reach the photomultiplier tubes.

$\alpha$-Particles, because of their charge and high decay energies, dissipate most of their energy in inelastic collisions with solvent molecules, with much of the energy being wasted in nonradiative losses. As a result, the fluorescence conversion efficiency for these particles is approximately an order of magnitude lower than for $\beta$-particles.$^{166}$ Complicating the discrimination between $\alpha$- and $\beta$-events in spite of the fact that $\alpha$-particles are much more energetic than $\beta$-particles.

In practice, discrimination between $\alpha$- and $\beta$-events is based on the characteristics of the light pulses produced by these particles in a scintillation cocktail. The high specific ionization of $\alpha$-particles gives rise to a delayed fluorescence component which results in light pulses of longer duration than those created by $\beta$-particles.$^{169}$ On this basis, $\alpha$- and $\beta$-events can be discriminated by analysing the shape of the respective light pulses.

8 MASS SPECTROMETRY

8.1 Inductively Coupled Plasma Mass Spectrometry

In recent years, an increasing number of researchers have explored the possibilities of ICPMS as an alternative technique for the determination of actinide nuclides at trace level.$^{123,170–175}$ ICPMS is an analytical technique that performs elemental analysis with excellent sensitivity and high sample throughput. ICPMS systems rely on the introduction of sample molecules into an argon plasma at temperatures of $6000–10000 \text{ K}$, where they are dissociated and the resulting ions are used into the plasma. Analyte ions are extracted from the plasma into a mass spectrometer (held at high vacuum) through a pair of orifices, known as sampling and skimmer cones. These ions are focused by a series of ion lenses into a magnetic quadrupole analyser, which separates the ions on the basis of their mass/charge ratio. The ion count is recorded for each mass number using, for example, a continuous dynode channel electron multiplier. Other detectors, such as discrete dynode multipliers and the Daly detector, have also been used to a limited extent.

A realistic LOQ for a conventional ICPMS system employing a pneumatic nebulizer and a quadrupole spectrometer is $\sim 2 \times 10^9$ atoms, at the present time. To illustrate, in the case of $^{239}$Pu, this is equivalent (in activity terms) to an LOQ of $\sim 2 \text{ mBq}$, which is a factor of $\sim 40$ higher (i.e. poorer) than conventional high-resolution $\alpha$-spectrometry. However, ETV of the sample can extend this limit down to $\sim 0.02 \text{ mBq}$ or slightly better, and new high-resolution ICPMS systems are just becoming available with a claimed LOQ approaching $10^6$ atoms. Using ETV ICPMS, LOQ values of 30 fg and 9 fg for $^{238}$U and $^{232}$Th, respectively, have recently been reported, both being blank limited.$^{176}$

In summary, for the assay of actinides, the latest ICPMS systems appear to be at least as sensitive as high-resolution $\alpha$-spectrometry, except for the shorter-lived $\alpha$-emitters (i.e. $t_{1/2} < 100$ years), where $\alpha$-spectrometry remains pre-eminent. ICPMS offers the great advantage of reducing counting times to a few minutes compared to the weeks-long counting times associated with $\alpha$-spectrometry.

8.2 Thermal Ionization Mass Spectrometry and Resonance Ionization Mass Spectrometry

In TIMS, samples are deposited on specially treated filaments, usually fabricated from rhenium or tantalum. The filament is heated slowly under closely controlled conditions to ionize the sample, which is then introduced
in the mass spectrometer. Because of isobaric and chemical interferences, it is necessary to first carry out a high quality chemical separation of the analyte element of interest.

LOQs with TIMS of $2 \times 10^6$ atoms for thorium and $8 \times 10^6$ atoms for plutonium have been reported.\(^{(177,178)}\) This is at least two orders of magnitude more sensitive than that attainable for the long-lived isotopes of these elements with conventional $\alpha$-spectrometry.

Resonance ionization mass spectrometry (RIMS) has also been shown to be a highly sensitive technique for the detection of trace elements. The method is based on the step-wise excitation of atoms from a defined state to highly excited states by resonant absorption of photons, followed by ionization with subsequent mass analysis of the ions. For neptunium, a detection limit of $4 \times 10^8$ atoms has been reported using this technique.\(^{(179)}\) RIMS has also been employed for the determination of uranium and plutonium.\(^{(180,181)}\) A detection limit for plutonium of $\sim 10^7$ atoms has been claimed.

### 8.3 Accelerator Mass Spectrometry

AMS is a highly sensitive technique for isotopic analysis in which atoms extracted from a sample are ionized, accelerated to high energies (mega electron-volts), separated according to their momentum, charge and energy, and individually counted (having been identified as having the correct atomic number or mass). The principal difference between AMS and conventional mass spectrometry is the energy to which the ions are accelerated (mega electron-volts as compared to kilo-electron-volts in conventional mass spectrometry). The practical consequence of operating at higher energies is that ambiguities in identification of atomic and molecular ions with the same mass are removed. This has made it feasible to use AMS to measure isotopic ratios as low as 1 in $10^{15}$. Moreover, this sensitivity can be achieved with sample sizes of a milligram or less (containing as few as $10^6$ atoms of the isotope of interest) within a measurement time of about an hour.

Although AMS is a relatively new and rapidly expanding field, various authors have already presented excellent reviews of the technology involved and the applications possible.\(^{(182–198)}\) Accordingly, only a brief description of the main features of actinide measurement by AMS will be given here.

In essence, the ion source (see section 6.3) produces a beam of (usually negative) ions (charge $q$), which are accelerated to energy $E$ (typically 100–400 keV) by a pre-accelerator and then separated according to their atomic mass ($M$) using a uniform magnetic field ($B$) directed normal to the plane of motion (momentum analysis). The radius of curvature ($r$) of the path of each ion is determined by Equation (8)

$$2 \left( \frac{ME}{q^2} \right) = k_1(Br)^2 \quad (8)$$

At this stage, ions with the correct $ME/q^2$ value are injected into a tandem accelerator, where they are accelerated to energies of some tens of mega-electron-volts. The ions also pass through a gas or foil stripper, which removes one or more electrons from the ions, forming multiply charged positive ions (charge $= +nq$). In addition, molecular ions with $n \geq 3$ are dissociated during the stripping process. The now positive ions are accelerated to ground potential before leaving the accelerator. Two or more magnetic and/or electrostatic selectors, placed after the accelerator, allow further rejection of unwanted ions. Magnetic analyzers select the correct ions on the basis of their $ME/q^2$ value, while electrostatic analyzers select the correct ions on the basis of their energy-to-charge ratio ($E/q$). A radial electrostatic field of constant magnitude ($\epsilon$) deflects the ions along a circular path of radius $\rho$ defined by Equation (9)

$$2 \left( \frac{E}{q} \right) = k_2 \epsilon \rho \quad (9)$$

In some systems, a velocity selector (Wien filter) is used instead of, or in addition to, an electrostatic analyzer. Finally, ions having the required mass and atomic number are identified and recorded using a suitable detector (e.g. longitudinal-field ionization chamber, time-of-flight system, Faraday cup, silicon detector). Such positive identification is necessary because ions other than those of the analyte nuclide may also reach the detector.

Several researchers have explored the application of AMS to the detection of heavy elements at trace level. Using AMS, Kilius et al.\(^{(191)}\) measured $^{230}$Th/$^{232}$Th ratios in uranium ore, thorium metal and uranium metal with high precision. Zhao et al.\(^{(192)}\) used AMS to measure $^{236}$U in uranium ore at a level of $\sim 10^{-10}$ relative to $^{238}$U. More recently, Purser et al.\(^{(193)}\) discussed in detail the design and operation of a novel AMS system, incorporating a 3-MV tandem accelerator, for the assay of actinide elements. It seems that the measurement of $^{236}$U in high-grade ore presents the greatest challenge, because the beam analysis system must completely eliminate ions of the other uranium isotopes (which are orders of magnitude more abundant in the sample material) since the detection system does not provide effective discrimination between $^{236}$U and $^{238}$U.

The absolute sensitivity of the AMS technique for actinide assay is perhaps best illustrated by the results of Fifield et al.,\(^{(166,161)}\) who demonstrated the capacity...
of the technique to measure plutonium at the 10<sup>6</sup> atom level. For 239Pu, this limit is also at least two orders of magnitude lower than that attainable with conventional α-spectrometry.

9 QUALITY ASSURANCE/QUALITY CONTROL

Although the application of well-tested analytical methods and good laboratory practices is an essential prerequisite for the production of high quality data, it is not, of course, a guarantee of the reliability of the data, and checks on the precision and absolute accuracy of the results should be part of every analytical program. In fact, the strengthening of national and international regulations, as well as the growth in the level of analytical work contracted out to commercial laboratories, require that radioactivity measurements be “traceable” to national and/or international standards, and that such traceability be supported by records of measuring equipment calibration, radiochemical procedures followed and quality assurance programs implemented.

Internal quality control can be achieved by means of the careful monitoring of field and reagent blanks, regular background determinations, periodic recalibration of tracers and detecting systems, and analysis of reference materials (RMs). The accuracy of the results obtained by a laboratory may be tested by participation in international intercomparison exercises such as those organized by the International Atomic Energy Agency as part of its Analytical Quality Control Services program. Intercomparison exercises are also organized by other organizations (e.g. National Institute of Standards and Technology (NIST)).

9.1 Traceability and Standardized Solutions

Traceability is defined as the property of a result of a measurement whereby it can be related to appropriate standards, generally national or international standards, through an unbroken chain of comparisons. The purpose of requiring traceability is to ensure that measurements are accurate representations of the specific quantity subject to measurement within the uncertainty of the measurement.

In low-level radioactivity analyses, reliable measurements must be traceable to recognized national and/or international measurement standards. A number of national laboratories, such as the National Physical Laboratory in the UK, NIST in the USA, Laboratoire Primaire des Rayonnements Ionisants in France and Physikalisch-Technische Bundesanstalt in Germany, provide low-level radionuclide standards directly traceable to absolute primary radioactivity standards. These and other national standards laboratories regularly participate in validation and intercomparison exercises organized under the auspices of the International Bureau for Weights and Measures to ensure traceability between different national standards.

α-Emitting radionuclide solutions for a number of actinides (e.g. 226Th, 229Th, 232U, 233U, 234U, 235U, 236U, 238U, 239Pu, 240Pu, 242Pu, 243Pu, 237Np, 241Am, 243Am and 244Cm) are available from these organizations and widely used as chemical yield monitors, as internal standards for radiochemical assay validation and for calibration of measuring instruments (e.g. α-spectrometers and mass spectrometers). These certified and traceable solutions are normally supplied in flame-sealed borosilicate ampoules, together with certificates detailing reference date of measurement, mass of solution, radioactivity concentration, assessment of uncertainty, method(s) of measurement, chemical composition of the solution, and recommended radionuclide half-life at the time of issue.

9.2 Field and Reagent Blank Analyses

The analysis of a field (or laboratory/reagent) blank to determine the true blank signal to be subtracted from the gross analyte signal is not a straightforward exercise. Ideally, a field blank should have the same composition as the sample, except that it should be free of analyte. Unfortunately, this is seldom the case in practice, and analysts all too often have to process blanks whose composition only crudely approximates that of the sample. Nevertheless, field and reagent blank analyses are essential, as they provide the only reliable means of determining whether contamination has been introduced into the samples as a consequence of in-field/in-laboratory contamination or via the chemical reagents used. For this reason, blank analyses should always be carried out with each batch of environmental samples processed.

9.3 Intercomparison and Reference Materials

Analysis of appropriate RMs represents the best and most direct way to investigate bias during analysis or to test the reliability of an analytical method. An RM is a material or substance for which one or more properties are sufficiently well established to be used for the calibration of an apparatus, the assessment of a measurement method, or for assigning values to materials. A certified reference material (CRM) is an RM where one or more of its properties are certified by a technically valid procedure, accompanied by or traceable to a certificate or other documentation which is issued by a certifying body.
A number of CRM s for radionuclide determination are available from NIST, covering a variety of radionuclides and environmental matrices in different concentration ranges. Uncertified natural matrix RMs are also available from the International Atomic Energy Agency in Vienna and from that Agency’s International Laboratory of Marine Radioactivity in Monaco. Materials on offer include soils, marine sediments, algae, biota and human and animal bone.

10 PERSPECTIVES AND FUTURE DEVELOPMENTS

There is little doubt that the use of mass spectrometric techniques for the assay of actinides at trace or environmental level will continue to increase at the expense of \( \beta \)-spectrometry. However, the latter will remain the method of choice for actinides and other \( \alpha \)-emitters with half-lives shorter than \( \sim 100 \) years, owing to its much higher sensitivity for such nuclides. Similarly, the technique of extraction chromatography is becoming increasingly popular for the sequential separation of actinides from different matrices, with the development of highly selective coated resins. Benefits claimed for this technique include higher chemical yields, reduction in analysis time with consequent savings in labor costs, and significant reductions in the quantities of waste chemicals produced.

One of the main drawbacks of analytical radiochemistry is the labor-intensive nature of the operations involved. Although attempts, some quite successful, have been made to part-automate the analytical steps required to separate and purify various actinides from natural matrices, it appears that industry is still some way from developing dedicated and fully automated systems with the full range of capabilities and the flexibility essential in what is, after all, one of the most demanding areas in analytical chemistry.

Standard RMs and, in particular, fully traceable reference solutions are vital tools in the complementary fields of analytical radiochemistry, \( \alpha \)-spectrometry and mass spectrometry. Unfortunately, there is reason to question the future availability of some of the most important tracers presently in general use, for example \( ^{242} \)Pu and \( ^{244} \)Pu. It is, therefore, incumbent on the scientific community, in association with international and national standards laboratories, to take the necessary initiative to protect the continued availability of as wide a selection of these tracers as possible. This should include surveying the user community as to their future needs. It is likely that one of these needs will be for tracers for chemical speciation analysis, a field of study that has attracted growing interest in recent years.

ACKNOWLEDGMENTS

We gratefully acknowledge the many colleagues and associates who generously advised and assisted us over the years in implementing a number of the analytical schemes and protocols described above in our own laboratory.

ACTINIDES AND OTHER ALPHA-EMITTERS, DETERMINATION OF

Radioisotopes have unstable nuclei that decay in a statistically predictable manner with the release of radiation in the form of particles or electromagnetic waves. In $\beta$-decay “fast electrons” called $\beta$-particles are released, which have a spectrum of kinetic energies ranging from near zero to a characteristic maximum ($E_{\text{max}}$). $E_{\text{max}}$ can vary by orders of magnitude among different types of emitters. The low mass of $\beta$-particles causes them to lose energy quickly through molecular collisions, producing excitation of valence electrons, ionization of atoms, and in some cases specialized radiation (bremsstrahlung and Čerenkov radiation, and Compton scattering). Detection of $\beta$-particle emissions is complicated by the wide range of possible energies and the weakness of some emissions, so that a single type of detector is inadequate for the analysis of radiation from all $\beta$-particle emitters.

Detectors are characterized by a sensitive volume in which particles interact with matter to produce a signal, an example of which is the emission of photons. The signal can produce a continuous current or a pulse. In pulse mode it is desirable to choose a detector such that the pulse is proportional to the energy of the particle, giving the instrument the property of energy discrimination. This property permits spectral analysis and methods of quantitation that are based in part on energy spectra. Liquid scintillation counting (LSC) is the most accurate and widely used method for detecting low-energy $\beta$-particles. Usually the information obtained by LSC must be corrected for signal loss due to absorption of incident particles or emitted photons. This signal loss is called quenching. For quantitation of low-energy $\beta$-radiation, quench corrections are usually made using the sample channels ratio (SCR) or an external standard method. All such calculations are subject to error and derived values are subject to the compounding of precision error during mathematical manipulation of the data.

Scintillation counting with organic crystal detectors is the method of choice for high-energy $\beta$-particle emitters. Gas-filled detectors are of limited value for $\beta$-particle detection, although windowless proportional counters are appropriate for detection of low-energy particles, especially in gaseous form. When neither energy discrimination nor precise quantitation is required, Geiger–Müller counters are acceptable for high-energy $\beta$-particle detection. They can detect all but the least energetic of low-energy emitters, although Geiger–Müller counters are not practical for the analysis of activity from such emitters because the signal is very weak, and the energies from incident particles are frequently absorbed before reaching the sensitive volume. Silicon-barrier semiconductors support energy discrimination and are of value for some applications. Visual imaging with photographic film is used for localization of $\beta$-particle emitter activity, as in labeling of biological tissues or macromolecules.

1 INTRODUCTION

This article is designed to assist a new investigator in selecting appropriate instrumentation for detection, qualitative analysis, and/or quantitation of sources of $\beta$-radiation for research or for quality control applications such as contamination monitoring for safety purposes. The target group includes investigators who are unfamiliar with radiation detection or who have
experience in measurement of $\alpha$- and/or $\gamma$-radiation but are not familiar with the requirements for accurate detection and quantitation of $\beta$-particle-emitting radionuclides.

Prior to selection of instrumentation, the investigator should be acquainted with the nature of $\beta$-decay and how $\beta$-particles interact with molecules of surrounding materials. Properties of detectors in general are discussed, and terminology of radiation detection is introduced. Criteria for the choice of detection method are presented along with a table outlining the advantages and disadvantages of the available detection methods for $\beta$-particles. Principles of operation and general operating procedures for useful detection systems are presented.

## 2 $\beta$-DECAY AND INTERACTIONS

### 2.1 Atomic Theory and Radioactive Decay

An atom exists as a positively charged nucleus surrounded by a number of negatively charged orbiting electrons. The nucleus consists of one or more positively charged protons, which give the atom its unique atomic number ($Z$), and a number of uncharged particles of similar mass, called neutrons. The identity of an element and its characteristic properties are conferred by its atomic number. The number of protons and neutrons combined give an element its characteristic atomic weight ($A$).\(^1\)

Most elements can exist in the form of different isotopes, because atoms can have the same atomic number but different numbers of neutrons. The isotopes of a given element all have the same atomic number but vary in atomic mass. Different isotopes of an element are designated by the nearest integer to the atomic mass. For example, the most common form of phosphorus, with atomic number 15, has an atomic mass of 30.98 g mol\(^{-1}\) and is designated phosphorus-31. Phosphorus-32 is a less common isotope of phosphorus. It has the same number of protons, hence the same atomic number, but has one more neutron than phosphorus-31. Stable isotopes are those for which spontaneous changes in atomic structure either are not known to occur, or occur at a negligible rate (see below for a more precise definition). Eighty-one elements with one or more commonly occurring stable isotopes are known, with atomic numbers ranging from 1 (hydrogen) to 83 (bismuth).\(^2\)

Unstable isotopes are any of those for which radioactive decay, in the form of changes in atomic mass, loss of energy, ejection of particles or photons, and/or atomic rearrangements, is known to take place. Atomic decay can result in the emission of one or more of several different types of ionizing radiation, of which $\beta$-radiation is one category. While the term isotope is used to refer to elements with constant atomic number but differing atomic masses, nuclide is a more general term used to distinguish any specific nuclear species such as tritium (hydrogen-3), phosphorus-32, or oxygen-16. The term radionuclide refers to any nuclide that is known to undergo radioactive decay.

The Heisenberg uncertainty principle requires that it is impossible to predict when a particular atom will decay. Thus, efforts to quantify ionizing radiation rely heavily on probability theory. For a known quantity of a radionuclide, it is predictable that within a given period of time a certain percentage of the material will undergo decay. The fundamental law of radioactive decay\(^3\) (Equation 1) predicts the rate of disintegration of a number of radioactive nuclei ($N$) from the decay constant ($\lambda$) for the nuclide.

$$\frac{dN}{dt} = -\lambda N \tag{1}$$

Perhaps a more familiar measure of decay rate is the half-life, which is the time required for one-half of the atoms of a radionuclide to decay. For a starting amount $A_0$ of radionuclide with decay constant $\lambda$, the amount $A$ remaining after time $t$ is given by the decay equation (Equation 2).

$$A = A_0 e^{-\lambda t} \tag{2}$$

From Equation (2), when $A = A_0/2$, the elapsed time $t$ gives the half-life of the radionuclide. Typical half-lives range from nanoseconds to several billion years. A stable nuclide can now be defined as an isotope for which no decay is observed to take place, or for which the half-life exceeds $5 \times 10^8$ years.

A reported half-life value for a radionuclide incorporates some assumptions. As a rule, the half-life of a radionuclide is independent of chemical bonding, the state of the matter, or environmental conditions such as temperature and pressure. However, chemical bonding has been observed to influence the half-life of radionuclides that undergo a particular type of decay, namely electron capture (section 2.2.3).\(^4\) A radionuclide may undergo more than one type of decay before a stable nuclide is attained. Furthermore, different paths to the stable nuclide or lowest energy state (ground state) are possible. Even with alternative decay schemes, a rate of decay can be measured and reported.

The traditional unit of radioactivity is the curie (Ci), in which 1 Ci consists of $3.7 \times 10^{10}$ atomic disintegrations per second (dps). This unit was developed from the best estimate for the decay rate of 1 g of pure radium-226.\(^5\) Research laboratories usually work with levels of activity on the order of millicuries (mCi) or microcuries.

\(Z\)-2.2  

\textit{b} emission is termed monoenergetic. When all emissions of a type have the same energy the reported and/or the spectrum is represented graphically. 

The number of specific activity include curies per gram (Ci g\(^{-1}\)) or becquerels per gram (Bq g\(^{-1}\)) 

The electron-volt (eV) is the traditional unit for measurement of the energy of radiation.\(^{[3]}\) One electron-volt is defined as the kinetic energy given to an electron as it is accelerated through a potential difference of one volt. Characteristic energies of ionizing radiations are in the range of thousands or millions of electron-volts (keV or MeV, respectively). The energy of radiation from a specific source may be distributed in a continuous spectrum, in which case the maximum energy \((E_{\text{max}})\) is reported and/or the spectrum is represented graphically. When all emissions of a type have the same energy the emission is termed monoenergetic.

### 2.2 \(\beta\)-Decay

When a decay process results in a change in the atomic number \(Z\) of a nuclide, but no change in atomic mass \(A\), the event is categorized as a \(\beta\)-decay. The change in \(Z\) takes place as a neutron is converted to a proton, or vice versa. Thus the atom is actually converted into a different element. \(\beta\)-Decay typically results in the ionization and/or excitation of electrons. An orbital electron exists in a stable bound state at a discrete energy level. Under quantum theory, a limited number of energy states is allowed for each electron. The process of excitation takes place when an orbital electron absorbs a photon whose energy is exactly equal to the difference between that electron’s energy state and a higher one, and the electron is excited to the higher energy state. De-excitation takes place when an excited electron drops to a lower discrete energy state, emitting a photon. The energy needed to remove an electron from its orbital is called its binding energy. When an electron absorbs energy in excess of its binding energy it is ejected from the atom and becomes a free electron, forming an ion pair in a process called ionization.

Two other major types of radioactive decay are \(\alpha\) and \(\gamma\), respectively. Upon decay, an \(\alpha\)-particle emitter ejects a helium nucleus, which is a particle consisting of two protons and two neutrons. The atom therefore loses two atomic number units and four atomic mass units. As with a \(\beta\)-particle emitter, an \(\alpha\)-particle emitter is converted to a different element upon disintegration. However, unlike a \(\beta\)-particle emitter there is a significant change in atomic mass.

\(\gamma\)-Decay usually is secondary to one of the previously discussed types of decay. The emission of particles during \(\alpha\)- or \(\beta\)-decay usually leaves the new nucleus in an excited energy state. \(\gamma\)-Decay involves a transition of the excited nucleus to a lower state, possibly the ground state, resulting in emission of a \(\gamma\)-ray photon. No change is seen in either atomic number or mass following \(\gamma\)-photon emission.

Three common types of \(\beta\)-radiation are recognized. In two of these modes the radiation is in the form of either a fast electron or a positron. The term “fast electron” refers to a free electron (i.e. one that is not in orbit about an atomic nucleus) with kinetic energy. In both types of decay the charged particle is called a \(\beta\)-particle, and its kinetic energy ranges from zero to a maximum that is characteristic of the radionuclide. A third common type of decay, electron capture, does not involve release of a particle but does result in emission of X-rays and Auger electrons (section 2.2.3). Other rare types of decay have been included in the category of \(\beta\)-particle emission but will not be treated in this article.

#### 2.2.1 Fast Energetic Electron (\(\beta^-\)) Decay

A plot of neutron-to-proton ratio for stable isotopes reveals that for nuclear stability to be maintained, the neutron-to-proton ratio increases with increasing atomic number from 1 up to 1.5 for the element bismuth (atomic number 83). Elements with atomic number greater than bismuth are all unstable. \(\beta^-\)-Decay is characteristic of nuclides with an unstable neutron-to-proton ratio in the nucleus, exceeding that of a stable nucleus.\(^{[1,2]}\) That is, nuclei with an “excess” of neutrons typically undergo \(\beta^-\)-decay. There is not necessarily a one-to-one correspondence between number of protons and number of neutrons, thus the word “excess”, used here, means “in excess of the number required to maintain a stable nucleus”. For example, the most common form of hydrogen consists of a proton with one orbital electron. Deuterium, a stable isotope, has one neutron in addition to its proton. The nucleus of tritium, which is unstable, consists of a proton and two neutrons.

During decay of a \(\beta^-\)-particle emitter, a neutron is converted to a proton, an electron, and an electron antineutrino (\(\bar{\nu}\)). The mass of the atom remains unchanged.
but the atomic number in this type of decay increases by one. For example, the common stable isotope of carbon has mass number 12 and atomic number 6. Carbon-14, an unstable isotope, has an atomic mass of 14, and an atomic number of 6. Following $\beta^-$-decay the mass number remains 14 but the atomic number increases to 7, and thus the carbon atom is converted to a nitrogen atom (nitrogen-14). Similarly, tritium has one proton and two neutrons, hence mass number 3. Upon decay, the nucleus is converted to a stable isotope of helium (helium-3), with two protons and one neutron. In $\beta^+$-decay the energy of disintegration can be calculated from the atomic mass energy difference between the radionuclide and the new nuclide that results from the decay, and the binding energy of the ejected electron.

The electron that is ejected from the nucleus during $\beta^-$-decay is a $\beta^-$-particle, also called a “fast electron” in reference to its kinetic energy. The kinetic energy of each $\beta^-$-particle is a fraction of the energy released in the disintegration process, with the remaining energy imparted to the antineutrino. The energy of disintegration is randomly shared among three entities, namely the nucleus, the $\beta^-$-particle, and the antineutrino. Thus, for any given type of $\beta^-$-particle emitter, the kinetic energies of the fast electrons vary in a continuous spectrum from zero, when all of the energy not imparted to the nucleus is given to the antineutrino, to a characteristic maximum in which all the energy is acquired by the $\beta^-$-particle and none by the antineutrino.$^{(4)}$ Each type of $\beta^-$-particle emitter has a unique energy spectrum with a characteristic energy maximum $E_{\text{max}}$ (Table 1), while emitters that decay by electron capture produce monoenergetic emissions.

For a comprehensive list of $\beta^-$-particle emitters and properties the reader is referred to published tables of isotope data.$^{(6)}$ For purposes of discussion, emitters with energy maxima of less than 500 keV are considered to be of low energy, while emitters with energy maxima greater than 1000 keV are considered to be high-energy sources. When measuring sources with energies between these values, instrumentation that is suitable for either range should be considered. Tritium should be considered separately as its energy maximum is nearly an order of magnitude lower than the next weakest $\beta^-$-source.

### 2.2.2 Fast Positron ($\beta^+$) Decay

Positron decay is characteristic of nuclides with an unstable excess of protons.$^{(2)}$ In this decay mode, a proton is converted into a neutron, a positron ($\beta^+$), and a neutrino ($\nu$). The mass number again remains the same, but the atomic number is reduced by one. The positron is also called a $\beta^+$-particle, just as a fast electron is called a $\beta^-$-particle in $\beta^-$-decay, but the symbol is written as $\beta^+$. An example of a $\beta^+$-emitter is sodium-22, half-life 2.6 years.$^{(1)}$ With sodium-22 about 90.5% of decay processes result in emission of a $\beta^+$-particle, while 9.5% occur by electron capture (described in section 2.2.3).

A positron is very short-lived, typically surviving less than a microsecond.$^{(1)}$ Annihilation with release of energy takes place the instant the positron encounters an electron, which usually occurs within the source itself (Figure 1). In the annihilation process the energy in the masses of the two particles is converted to electromagnetic radiation, and the two photons are emitted in opposite directions (i.e. anticoincident photons), conserving linear momentum.$^{(4)}$ The kinetic energy associated with either incident particle is negligible compared with its resting mass energy of 0.51 MeV. Thus, detection of $\gamma$-photons with energy of 0.51 MeV is indicative of positron decay. Readers interested in detection of annihilation photons are encouraged to consult articles on $\gamma$-radiation determination.

### 2.2.3 Electron Capture

An alternative decay mode resulting from an excess of protons involves the capture of an electron from the

2.3 Interactions with Matter

The primary focus of this section will be interactions involving \( \beta^- \)-particles. In addition, a phenomenon known as Compton scattering, which is characteristic of the interaction of photon radiation with matter, will be discussed because of the significance of Compton scattering in the use of external standards for scintillation counting (section 4.3.3.3).

In these discussions the emitted particles will be called the incident particles while the particles with which they interact will be called target particles. This article will at times use the term collision to describe an interaction between two subatomic components. It should be noted here that the term collision, while convenient, does not accurately describe interactions of radiation with matter. Particles do not physically collide as billiard balls collide in classic physics experiments; the interactions are more complex, although superficially they resemble events that we commonly call collisions for example, the most common target particles of ionizing radiation are orbital electrons. An interaction between a \( \beta^- \)-particle and an orbital electron is in the form of an electrostatic force. In addition to electrons, target “particles” can also include nuclei, nucleons, or whole atoms. In all cases, the interactions are best described in terms of quantum physics, but for the purposes of this article the term collision will suffice.\(^4\)

\( \beta^- \)-Particles can cause ionization and excitation of atoms and molecules as well as types of interaction that are not characteristic of heavy particle interaction. These include emission of bremsstrahlung (section 2.3.2) and Čerenkov (section 2.3.3) radiations.\(^5\)

\( \beta^- \)-Particles tend to follow a tortuous path when encountering matter because, since they are themselves electrons, the mass of the particle is equal to that of an orbital electron. \( \beta^- \)-Particles tend to lose energy at a slow rate compared with heavy charged particles such as \( \alpha \)-particles. Multiple interactions are possible, with the number of likely interactions and changes in direction depending on the initial kinetic energy of the particle (Figure 2).\(^3\)

\subsection{2.3.1 Ionization and Excitation}

Passage of a \( \beta^- \)-particle through a medium results in ionization and/or excitation of atoms. Ionization takes place when the energy transferred to an orbital electron exceeds the binding energy of the electron, causing the target particle to be ejected from the atom and creating an ion pair (Figure 3). Since a \( \beta^- \)-particle and an electron are of equal resting mass the result is a considerable loss of energy on the part of the incident \( \beta^- \)-particle and scattering of both the incident particle and electron in new directions. The secondary electrons that are so produced have sufficiently high kinetic energies to cause additional ionization and/or excitation events.

Typically about half of the energy in a \( \beta^- \)-particle is dissipated through ionization while the other half is dissipated through excitation.\(^4\) When the energy transferred to an orbital electron is less than the binding energy the result can be excitation of the electron to a higher energy state, as shown in Figure 4. De-excitation results in the emission of a photon.

\subsection{2.3.2 Bremsstrahlung Radiation}

Bremsstrahlung radiation (braking radiation) becomes important as the atomic number of the radionuclide
2.3.3 Čerenkov Radiation

Very high energy emitters can produce β-particles that travel faster than the speed of light in a particular medium, such as water or clear acrylic. This produces a kind of “shock wave” similar to that produced when an object exceeds the speed of sound in air. As the particle is slowed by the medium, visible photons in the blue-white region of the spectrum are emitted. Čerenkov radiation is responsible for the blue glow in water used as a cooling medium for nuclear reactors.

The detection of Čerenkov radiation is of interest in high-energy physics, and is beyond the scope of this article. Specialized devices used for detection of Čerenkov radiation are based on detection of this “Čerenkov light”.

2.3.4 Compton Scattering

Compton scattering results from the interaction of a photon with an electron in the absorbing material. The effect deserves mention here because of the use of γ-ray sources as external standards in scintillation counting. Any photon with sufficient kinetic energy, such as those emitted by γ-ray or X-ray sources, can cause the Compton effect. Energy is transferred from the incident ray to a target electron, leaving the photon with less energy than prior to the “collision” and ejecting an electron with kinetic energy nearly equal to that lost by the incident ray (Figure 6). There is much variation in the amount of energy transferred to the target electron during such events, as well as variation in direction of the electrons. Electrons that are scattered in this manner are known as recoil or Compton electrons.

Compton electrons interact with matter in a manner identical to β−-particles. The energy distribution due to Compton electrons is characterized by an abrupt increase in the distribution of energies near the high-energy end of
The principles on which detection of $\beta$-radiation is based include production of a measurable signal by ionization and/or de-excitation, where the size of the signal is proportional to the number of ion pairs or photons produced. Many factors participate in the determination of the number of such events per particle; however, for quantitation purposes the size of the signal is treated as proportional to the initial kinetic energy of the $\beta$-particle.

### 3.1 General Properties of Instrumentation

#### 3.1.1 Detectors

An instrument designed for the detection and measurement of $\beta$-particle emissions consists of a detector (in which ionizing radiation produces a signal) and a signal processing mechanism. A detector has three principal components. Radioactive decay takes place in a sensitive volume in which interactions between ionizing radiation and matter take place, producing ion pairs and subsequent events that can be detected. The sensitive volume requires a housing, the properties of which can be critical to the purpose of detection. The final component is a mechanism for delivery of a signal to a processing system. The sensitive volume can be a gas (ionization chambers, proportional counters, Geiger–Müller counters), a liquid (liquid scintillation counters), or a solid (semiconductor detectors, organic crystal detectors).

When ionizing radiation passes through a gas it can leave a trail of positive and negative ions, which migrate in an electric field. This generates a current that is directly proportional to the number of ion pairs produced. The generation of electric current by the formation of ion pairs in an electric field is the basis for detection by gas-filled detectors and semiconductor detectors. Excitation of electrons by either $\beta$-particles or secondary electrons leads to fluorescent de-excitation, which can be detected by a light-sensitive device such as a photomultiplier tube (PMT). Scintillation counters and Cerenkov detectors both use light emission as a signal source.

#### 3.1.2 Modes of Operation

A detector can be operated in current mode, in which the detector measures the average direct current resulting from $\beta$-particle emissions and subsequent interactions within a sensitive volume. This form of signal processing does not discriminate between individual events, but rather the signal is an average current that depends on the number of events per unit time and the average number of charge carriers produced per event. For most laboratory applications a current mode of operation is inappropriate, since no information about the energy distribution of decay events is available. A current mode of operation is suitable when the intent is simply to monitor high-energy radiation from a known source, for example to detect fluctuations in radiation levels in a nuclear reactor.

Most detectors operate in pulse mode, in which each quantum of radiation that produces a measurable signal is recorded as a separate event. A pulse mode of operation can return the number of $\beta$-particles produced per unit time as well as the distribution of energies of the particles. The information obtained is essential to most forms of analysis. In pulse mode a detector returns a count rate, or counts per minute (cpm), the value of which is proportional to, but seldom equal to, the rate of actual radioactive decay (disintegrations per minute, or dpm).

#### 3.1.3 Detector Efficiency

Efficiency ($\varepsilon$) of detection is a critical property of any radiation detector. Efficiency can be defined as the ratio of events recorded per unit time to the actual number of atomic disintegrations taking place in the sample during the same time period. The latter value is usually reported as dpm, or less frequently as dps. In pulse mode, efficiency would therefore be reported as cpm/dpm. Efficiency is affected by the properties of the detector as well as the type and energy of the emitter, the physical or chemical form of the emitter, and the surrounding gas, solvent molecules, or impurities that may interfere with detection or contribute spurious counts. Factors that may contribute to the efficiency with which $\beta$-decay is recorded are described next.

The geometry of a detector puts some limit on the number of radiations that are emitted in the direction of the sensitive volume. For example, in LSC photons must strike the sensitive surface of a PMT to record a count. Signals will be missed due to geometric constraints unless the sensitive surface completely surrounds the sample and all parts of the vial containing the sample are transparent to photons. In proportional counters samples can be introduced as a film on a support surface with only one side exposed to the sensitive volume. This would be described as a $\pi$ counter, describing the angle subtended by the detector. If the sample is exposed on all sides of a support, the counter is described as having $4\pi$ geometry.
Some fraction of radiations may not reach the sensitive volume for reasons other than the geometry of the detector. The same types of interactions that take place between \( \beta \)-radiation and matter in the sensitive volume can take place within the sample itself, involving the radioactive nuclide, nonradioactive isotopes of the nuclide, contaminating materials, solvent molecules, etc. The result can be self-absorption, namely scattering of energy from radioactive decay before the signal leaves the sample. Depending on detector type, radioactive materials may be separated from the sensitive volume by a barrier called a window. A properly designed window should be transparent to measured radiation, but some attenuation may take place due to interactions of ionizing radiation with materials of the window itself. Loss of signal can also result from interactions with air molecules between the sample and the window. These types of losses, called material attenuation, are a major problem with detection of \( \beta \)-radiation, particularly from low-energy sources. In fact, the fraction of radiation from low-energy \( \beta \)-particle emitters that reaches the sensitive volume is usually quite small unless the sample is incorporated directly into the sensitive volume itself.

Efficiency is affected by the probability of the radiation actually interacting with the sensitive medium and producing a signal. This is of less concern when measuring \( \beta \)-radiation, since typically nearly 100\% of charged particles do react with the sensitive volume.\(^4\)

The efficiency of actual data recording is affected by several intrinsic factors not related to the sample itself, including detector dead time losses, coincidence losses, and incomplete capture. Dead time losses stem from the fact that the detector and/or signal processing mechanism may be inactive for a period of time following detection of an event.\(^5\) Coincidence losses result from the occurrence of two or more nearly simultaneous decay events which are recorded as a single event of higher energy. Coincidence losses are a major factor when specific activities are very high with correspondingly high count rates.

### 3.1.4 Background

Radiation from sources other than the source to be analyzed contribute to the sum total of counts recorded. Typical sources of this background radiation include radioactive impurities in the constituent materials of the detector itself, as well as in the environment surrounding the detector. All materials including the atmosphere itself contain some background activity. Sources can be nearby or far away depending on the type of emitter. For example, a common source of background radiation in LSC is potassium-40, present as a small fraction of the natural potassium that is a component of glass vials. Cosmic radiation also produces a constant background radiation. To the extent that background radiation is not distinguishable from experimental activity, counts due to background are unavoidably included with counts recorded from the intended source.\(^3\)

If emissions from the sample to be analyzed are low enough that the background contribution is significant, correction can be made by counting samples of identical composition but without the radionuclide of interest. For example, in LSC background counts are determined by counting a vial with the same volume and type of cocktail, but containing “cold” samples (samples treated identically to the labeled samples, but without radioactivity). Modern instruments can be programmed to automatically subtract background counts. However, background radiation is normally so low relative to source emissions that its contribution can be ignored.\(^4\)

Under some circumstances background is sufficiently high to be a problem. In laboratories near accelerators, reactors, or in environments with extensive use of high-energy emitters, appropriate shielding may be necessary to reduce background radiation. Unfortunately, the shielding itself is often a source of background radiation due to impurities in the construction materials.\(^4\) Shielding does not protect experiments in which very low levels of radiation must be detected. When the source is extremely weak, the investigator may have to resort to use of statistics to detect radiation from the source to be analyzed, over and above the counts due to background.

Spurious counts can be produced by such phenomena as chemiluminescence, which is sometimes encountered in LSC. PMTs are sensitive to fluctuations in supplied voltage and may deliver spontaneous pulses.

### 3.1.5 Signal Processing

The simplest pulse-mode processors only provide an output of cpm, and do not resolve the energies of individual emissions. A portable Geiger–Müller counter usually provides an analog output in the form of a galvanometer needle or audible clicks. Sophisticated processors can sort measured energies for individual emissions into specific channels or windows. Here the term window should be distinguished from its other use, to describe any barrier between a radioactive source and the sensitive volume of the detector. Rather than lumping all counts, regardless of energy of the source emission, into a single count total, each detected event can be logged as a count into one of two or more channels, each representing a specific range of apparent energies. By obtaining count totals for specific energy ranges, activity due to different emitters within a sample can be determined (see section 4.3.5), and signal losses can often be corrected (see section 4.3).
Processors can perform complex calculations to correct for signal losses resulting from detector geometry, inefficient capture, and other causes. Processors frequently include coincidence circuits to ensure that the pulse originated in the sensitive volume rather than in the detection device itself. Background radiation can be counted and automatically subtracted from experimental counts, and statistical calculations can be made to ensure consistent performance and efficient use of the instrumentation.

### 3.2 Choice of Detection Method

No single detection method is favorable for both low-energy and high-energy $\beta$-particle detection and measurement. Low-energy $\beta$-particles are readily stopped by physical barriers such as transparent windows between the source and the sensitive volume. Emitters with very low energy, especially tritium, have an extremely limited range in air alone. Even within a sensitive volume, a portion of the energy of a low-energy $\beta$-particle may be lost through interactions that produce no signal, such as absorption by impurities in the source. On the other hand, high-energy emitters require a sensitive volume of greater density and stopping power, so that all or most of the energy will be dissipated within the sensitive volume. For example, in a small volume a $\beta$-particle with high energy may penetrate the entire sensitive volume and collide with the wall of the detector itself. The escape of both high-energy $\beta$-particles and secondary radiation complicates attempts at energy discrimination.

The following questions should be considered when selecting a detection method:

- What specific emitters will be analyzed?
- Will detection be limited to low-energy $\beta$-particle emitters or low- and high-energy emitters?
- Will the same instrument be needed for detection of other types of radiation?
- Will it be necessary to count one type of emitter in the presence of another? (Detection methods that are suitable for $\beta$-particle determination may be entirely inappropriate for measurement of other types of radiation.)
- What is the nature of the application? For example, is simple detection all that is required, such as for contamination monitoring or detection of the presence/absence of label, is quantitation of activity necessary for analytical methods such as radioimmunoassays, or is there a need to obtain an energy spectrum for an unknown source?

The physical state of the radionuclide (gaseous, liquid, solid) in part determines the suitability of a particular method as well.

Ionization chambers are generally used for measurement of gaseous samples, but they are not suitable for detection of $\beta$-particle emitters. Many common $\beta$-radiation sources in laboratory use emit in the low-energy range, with $E_{\text{max}}$ of less than 0.5 MeV. Provided the source is liquid or can be dissolved in liquid, LSC is by far the most suitable method of detection for most such applications. Proportional counters are also used for detection of low-energy emitters. Geiger–Müller counters can efficiently detect only the higher energy emissions and are not suitable for quantitation of low-energy $\beta$-particle activity, or for energy discrimination in any case. High-energy (>1 MeV) emitters can be detected using Geiger–Müller counters and spectra analyzed using scintillation counting with organic crystals. Table 2 lists recommended instrumentation for high- and low-energy $\beta$-particle determination. As suggested in the table, LSC offers the most versatile method of $\beta$-particle detection, and is the recommended detection method for the vast majority of individual laboratory applications.

### 3.3 Error Analysis, Statistics, and Quality Control

#### 3.3.1 Counting Statistics

When any variable that is subject to statistical fluctuations is measured repeatedly, variation is observed among

measurements. Provided the experiment is well controlled and there is no bias in the sampling method, the values of individual measurements should be distributed symmetrically about a single value, called the sample mean or experimental mean \( \bar{x} \). The determination of counting rates is subject to statistical principles as well. If a sample with a relatively long half-life of known activity is counted for a fixed period of time and the count is repeated several times, each count typically yields a different value due to statistical variation.

In the field of statistics the true mean \( \bar{x} \) is the average value of a measurement that would be obtained if every possible experiment could be conducted. In effect, the total number of samples \( n \) would be infinity. The experimental mean is an estimate of the true mean obtained by repeated sampling (Equation 3).

\[
\bar{x}_e = \frac{\sum x_i}{n}
\]

The distribution of individual data points \( (x_i) \) about the experimental mean can be represented by a single number, the variance \( s^2 \) (Equation 4).

\[
s^2 = \frac{\sum (x_i - \bar{x}_e)^2}{n}
\]

When a large number of samples is taken (usually >30) then a Gaussian or normal distribution can be used as a model for the distribution of individual data points about a mean. Applying a normal distribution to an experimental sample, the square root of the variance (called the standard deviation, \( \sigma \)) can be used to estimate the probability that an experimental mean is within a given percentage difference of the true mean. In this model the probability that the true mean is within one standard deviation of an experimental mean is 68.3%. The probability that it is within two standard deviations is 95.5%, and for three standard deviations it is 99.9%. To obtain a probability of less than 0.05 that an experimental mean is within a predetermined fraction of the true mean, sufficient data must be collected so that \( 2\sigma /\bar{x}_e \) is one-half of that fraction.

The notation \( s^2 \) applies to variation among an infinite number of samples; that is, \( s^2 \) is the variance that would be obtained if all possible experiments were to be performed. Experimental data represent a subset of this universe, thus a calculated variance is only an estimate of \( s^2 \). Furthermore, \( s^2 \) is underestimated when calculated from a data set, thus a truer estimate of \( s^2 \) is given by the experimental variance \( s^2 \) (Equation 5). The experimental standard deviation \( s \) is then used as an estimate of \( \sigma \).

\[
s^2 = \frac{\sum (x_i - \bar{x})^2}{n - 1}
\]

Suppose the investigator wishes to be confident that an experimental mean is within 1% of the value of the true mean, with a confidence level of <0.05 (<5% probability that the experimental mean is outside this limit). Then the true mean must be within the range \( \bar{x}_e \pm 0.005\bar{x}_e \), that is, \( \pm 0.5% \). To reach the desired level of confidence, sufficient data must be collected so that twice the standard deviation is equal to 0.005\( \bar{x}_e \), or, \( \sigma = 0.0025\bar{x}_e \). For example, suppose an experimental mean is determined to be 40,000. Data points should be collected until \( \sigma = (0.0025)(40000) = 100 \).

The application of this method of assurance to a set of repeated measurements of the same variable is fairly straightforward. In counting radioactivity, however, there is a complication. An estimate of the actual rate of atomic disintegrations (dpm) is made for a sample by counting the activity for a set period of time, at the end of which the total counts divided by minutes of counting is used to determine cpm; cpm are then corrected to obtain dpm (these terms were defined in section 3.1.3). It would be trivial and time-consuming to make repeated counts, average them and obtain mean cpm, variance, and standard deviation in the manner of repeated sampling. In fact, to the extent that statistical theory is based upon the probability of occurrence of real events rather than rates or other derived quantities, this approach would be incorrect.\(^{(3)}\) An estimate of cpm in a sample is best determined from a single count \( x \), collected over a set period of time. Thus the number of samples is one. The experimental mean is in fact equal to \( x \), and \( s^2 \) cannot be calculated. For this situation the best estimate of the true variance is given by Equation (6).

\[
\sigma^2 \equiv s^2 = \bar{x} = x
\]

The standard deviation is therefore best estimated by Equation (7).

\[
\sigma \equiv \sqrt{s^2} = \sqrt{x}
\]

Using this model to obtain a probability of less than 0.05 that a cpm estimate is within a predetermined percentage of the cpm that correspond to the true dpm for the sample, twice the square root of the total counts must be less than or equal to half that percentage. For example, for a desired accuracy of 1%, twice the square root of total counts must be less than or equal to 0.5% of the total. That level is reached when total counts reach 160,000 (Equation 8).

\[
\frac{2\sqrt{160000}}{160000} = 0.005
\]

When activities of samples vary considerably, the maximum counting time should be set in order to obtain a reasonably accurate count for the samples of lowest
expected activity. The instrument can be programmed to interrupt counting of a more active sample and move to the next sample when the desired level of accuracy is obtained. For example, programmable Beckman liquid scintillation counters allow the operator to select a “2σ (\%)” value, which is simply 200 divided by the square root of the total count. Selection of a 2σ (\%) value of 1.00 causes the instrument to cease counting when the total count reaches 160 000. Note that this method of error estimation is independent of the time of counting, and relies only on the total count obtained. In the example above counting would be interrupted whether it took 5 s or 5 min to reach 160 000. This allows for more efficient operation by avoiding prolonged counts and returns results more rapidly than if all counts were performed for a fixed interval.

In obtaining derived values from counts, such as ratios, rates, or other numbers that require various functional manipulations, the investigator must be aware that any uncertainty in the original measurement is carried throughout the process. The magnification of error in the course of obtaining calculated values is called error propagation.\(^{(11)}\) The use of the same specific count more than once in arriving at a calculation should be avoided since this complicates error determination.\(^{(11)}\) Let \(A\) and \(B\) equal two separate counts, with \(a\) and \(b\) the respective errors, so that count \(A\) can be represented as \((A \pm a)\) and count \(B\) can be represented as \((B \pm b)\). When multiplying or dividing either quantity by a constant, the error is multiplied or divided by the same constant. The error resulting from either summing \(A\) and \(B\) or subtracting one from the other is given by \(\pm(\sqrt{a^2 + b^2})^{1/2}\). The product of \(A\) and \(B\) yields the error \(\pm(ab)\). For \(A\) divided by \(B\) the error is given by Equation (9).

\[
\text{error} = \pm\left(\frac{a^2}{B^2} + \frac{A^2}{B^2}b^2\right)^{1/2}
\]

### 3.3.3 Quality Control for Instrumentation Performance

Instrumentation can be periodically checked by taking a series of counts while keeping the conditions as consistent as possible. Typically this might be 20–50 one-minute counts. An experimental mean is calculated and a chi-squared (\(\chi^2\)) test conducted to determine if the experimental data fit a Gaussian distribution. The value of the \(\chi^2\) statistic is given by Equation (10).

\[
\chi^2 = \frac{1}{\bar{x}_e} \sum (x - \bar{x}_e)^2
\]

If the individual counts do represent a normal distribution then the sample variance \(s^2\) should equal the mean, which is assumed to be equal to the true variance \(\sigma^2\). If the number of individual counts is \(n\), then \(\chi^2\) is related to \(s^2\) by the relationship in Equation (11), in which \(n - 1\) represents the number of statistical degrees of freedom.

\[
\chi^2 = \frac{(n - 1)s^2}{\bar{x}_e}
\]

The deviation of the ratio of \(s^2\) to \(\bar{x}_e\) from unity indicates the deviation of the sample data from the theoretical distribution. To estimate the probability that the difference in distribution of experimental data from the statistical model is not due to chance the \(\chi^2\) statistic should be calculated, and the probability determined from a \(\chi^2\) distribution table.

### 3.3.3 Quality Control for Radiation Safety

High-energy \(\beta\)-particle emitters such as phosphorus-32 release \(\beta\)-particles that can travel in air up to 6 m from the source, the length of a typical laboratory bench. Thus high-energy emitters represent an exposure hazard that requires shielding for protection of personnel. An acrylic shield with a thickness of 1 cm or greater effectively stops \(\beta\)-radiation from phosphorus-32. A survey meter (portable Geiger–Müller counter) can be used to detect contamination of benches, sinks, or instrumentation by a high-energy emitter. Radiation from low-energy emitters may travel as little as a few inches in air, and may not be sufficiently energetic to penetrate the window of a Geiger–Müller counter. Such emitters do not represent a major exposure hazard, but certainly represent an ingestion or direct contact hazard.

The form of the radionuclide affects the hazard level of the substance. For example, carbon-14 bound to carbon dioxide represents a very low hazard since carbon dioxide is quickly diluted in air and is not sequestered in the human body. Radioactive iodine vapors are in fact absorbed and accumulate in the thyroid gland to levels that can pose considerable risk. Tritium is the weakest \(\beta\)-particle emitter in common use, but its incorporation into biomolecules that are involved in biosynthetic pathways creates a moderate ingestion hazard. Tritium is undetectable by any device in which a window separates the source material from the sensitive volume.

In most laboratories using \(\beta\)-type radionuclides, wipe tests for contamination are regularly conducted. Most safety protocols require that wipe tests back up results obtained from a Geiger–Müller counter when using higher energy emitters. Wipe tests are essential for detection of contamination from very-low-energy emitters such as tritium and carbon-14. To conduct a wipe test following normal clean-up, a piece of filter paper or a cotton swab is dipped in an appropriate solvent and then wiped over the surface to be tested, usually covering 100 cm². The activity is then counted either by LSC (any \(\beta\)-particle
emitter) or organic crystal scintillation counting (high-energy emitter). Safety protocols always specify an action level: a significant number of cpm over background at which an area is determined to be contaminated. When the action level is exceeded, the contaminated area should be cleaned and re-tested.

4 SCINTILLATION DETECTORS

4.1 Principles

4.1.1 The Scintillation Process

When an incident emission contacts molecules of any material, it excites a number of electrons to a higher energy state, resulting in the emission of ultraviolet (UV) or visible light upon decay of the electrons to the normal state. The light flash that results is called a scintillation event, and materials that emit the light are called scintillants. In scintillation counting, materials are selected so that the energy from the $\beta$-particle emission is efficiently transferred to molecules of the scintillant and the event can be detected by measuring the light emitted following de-excitation of electrons in the scintillant. Theoretically any material is a potential scintillator, however materials used for radiation detection are selected based on several criteria.

- To be a useful material for $\beta$-particle detection, scintillation must take place immediately upon interaction with a $\beta$-particle, that is, it must have the property of fluorescence. Delayed emission of photons, called phosphorescence, would make quantitation difficult or impossible.
- To relay information efficiently, upon de-excitation the scintillant must emit a large fraction of the incident energy as light rather than heat (a radiative process).
- A material used as a scintillant must not absorb its own emissions. The material must be transparent to the wavelengths emitted during the scintillation process.

4.1.2 Scintillator Materials

Organic scintillators include crystals, liquids, and plastic. $\beta$-Particle-emitting radionuclides can be measured using organic crystals such as anthracene and stilbene. $\beta$-Radiation can also be assayed by direct incorporation of the source in plastic during polymerization. However, organic liquids consisting of solvent and dissolved scintillator molecules are most often employed for determination of $\beta$-activity. Solvents of choice include toluene, xylene, and 1,4-dioxan. The system may include a single organic scintillator, in which case it is known as a binary liquid scintillator, or it may include a primary and a secondary solute to improve the efficiency of detection of events. Useful primary solutes include 2,5-diphenyloxazole (PPO) and 2-phenyl-5-(4-biphenylyl)-1,3,4-oxadiazole (PBD). The most commonly used secondary solute is 1,4-di-[5-phenyloxazolyl]-benzene (POPOP).

Inorganic scintillators include crystals, glasses, and gases. Alkali halide crystals such as sodium iodide or cesium iodide are the most widely used in scintillation detectors. They are more commonly used for measurement of $\gamma$-radiation, since energy transfer from $\gamma$-radiation is much more in a crystalline medium than in a liquid medium. They can be used for high-energy $\beta$-particle measurement as well, but an organic scintillator is preferred for high-energy $\beta$-particle detection.

4.1.3 Detection and Quantitation

Light emitted by the scintillation process is often in the UV range, requiring specialized UV-transparent materials or conversion to visible light. Visible light emitted by detection systems is usually too weak to be seen with the unaided eye, so sensitive PMTs are used to record scintillation events. Because weak light emissions are measured, the samples must be counted in complete darkness. Scintillation counters are constructed with a conveyor system that indexes samples, one by one, into a dark chamber containing the detection apparatus.

Photons emitted by scintillation materials enter a PMT through a semitransparent window, then generate free electrons through interaction with photosensitive material on the inside of the window. The electrons are accelerated toward an electrode called a dynode which is coated with material that is capable of emitting secondary electrons. Secondary electrons are produced through a series of dynodes of increasing positive charge, producing an amplification cascade resulting in the collection of a large number of electrons at the anode. A PMT has a fixed gain so that it functions as a high-gain amplifier. Because the pulse emitted by the PMT is proportional to the initial number of incident photons, the use of PMTs permits energy discrimination by the collector apparatus.

In scintillation counting, signals of different pulse heights are sorted into channels or windows which are determined by discriminator settings. A channel consists of a specific range of pulse heights and is determined by upper and lower discriminator settings, which are simply upper (ULs) and lower limits (LLs) for pulse heights that will be recorded in the channel. Discriminator settings are divided arbitrarily throughout the entire range of possible pulse heights—for example, from 0 to 1000. Usually two or three channels can be established for a count.
4.2 Liquid Scintillation Detectors

LSC is widely employed in the life sciences, including biomedical and biochemical research, when assay of low-energy $\beta$-particle-emitting radionuclides is essential. In LSC the source is dissolved in an organic solvent along with the scintillation materials. The incorporation of the radiation source into a liquid brings the source as close as possible to the scintillant molecules, thus making it possible to accurately record radiation from weak sources. The solvent system must be capable of dissolving the primary and/or secondary solute as well as the radiation source. In biology and medicine the source of radiation is often in an aqueous solvent, so the carrying capacity for water in the organic solvent can be a limiting factor. Modern systems contain emulsifiers and other additives that improve the capacity of the solvent for aqueous materials. A complete liquid system including solvent, additives, and primary and secondary solutes is called a cocktail.

In a binary liquid system, the $\beta$-particle interacts with the solvent molecules, causing ionization and excitation. Energy transfer among solvent molecules continues through molecular collisions throughout the medium.\(^7\) Collisions with primary solute molecules result in excitation and de-excitation and the emission of photons. The wavelengths of photons emitted by primary solutes are usually within the UV range. The walls of glass vials would absorb such emissions, so special materials such as silica windows are needed to permit detection of UV light by a PMT. Secondary solutes serve as wavelength shifters, absorbing emissions from the primary solutes and emitting light in the visible range. Such emissions are not absorbed by clear glass. To serve as a secondary solute the material must have a lower excitation potential than the primary solute, which in turn has a lower excitation potential than the solvent molecules.

In addition to the problem of dissolving the source material, a disadvantage of LSC is the reduction or loss of signal due to (1) absorption of excitation energy by chemicals in the cocktail, (2) absorption of light by colored impurities in the system, or (3) radiation quenching due to differences in the effectiveness of energy transfer by radiations of different types and intensities.

4.3 Quenching and Quench Correction

4.3.1 Chemical Quenching

In the process of chemical quenching, impurities in the system absorb excitation energy, preventing transfer of energy from the solvent to the primary solute. The energy is converted to heat rather than light, and the signal is reduced. When weak radiation emissions are involved, the signal often goes undetected. Common sources of chemical quenching include the original solvent, often water, acidic or basic solutes that may have been used to solubilize the source, various salts and other impurities, and the source molecules themselves.

Chemical quenching may be unavoidable, particularly if a primary cause is the source molecule itself. Fortunately, chemical quenching is correctable using the SCR or Compton edge method. Figure 8 represents the distribution of pulse heights that would be observed from an unquenched sample versus a severely quenched sample.

4.3.2 Color Quenching

Color quenching results from the absorption of light emitted by either the primary or secondary solute, or both, by colored compounds in the source materials or solvent. A common source of color quenching in biomedical work is hemoglobin, for example. The degree of quenching depends on the properties of the absorbing substance, thus it is problematic to establish a quench curve as for other forms of quenching. Color quenching must be prevented by removal or bleaching of the interfering substance before the sample has been prepared for counting.

4.3.3 Quench Correction

4.3.3.1 Internal Standardization  

In the internal standardization method for quench correction, the efficiency of counting is measured directly by adding a known quantity of radioisotope to each sample, and relating cpm to known dpm.\(^7\) Each sample is first counted in the normal manner, then a standard quantity of the same radionuclide is added to each vial and the vials are re-counted. The efficiency of counting is given by Equation (12). The standard must be the same type of emitter as is present in
the unknown sample, to ensure that the quenching effect is the same on both. To avoid statistical error in determining efficiency, the specific activity of the standard must be considerably greater than that of the sample.

\[
\text{fractional efficiency} = \frac{\text{recorded channel 1 cpm}}{\text{known dpm in the sample}}
\]  

(13)

Although this method has the advantages of simplicity and rapidity, there are disadvantages. Once the standard has been added it cannot be removed, so the sample is irreversibly altered. The solvent containing the standard may actually introduce an additional quenching agent. Additional hazards are created by the need to open sample vials and add additional substances. The use of expendable standards with high specific activity rather than sealed quenched standards presents a disposal problem.

4.3.3.2 Sample Channels Ratio Quench correction by the SCR takes advantage of two situations. First, \(\beta\)-particles are released with energies ranging from zero to some characteristic maximum. Second, quenching reduces the recorded pulse height in response to higher energy decay, in addition to abolishing the signal from the lowest energy events. Quenching causes a shift in the proportion of pulses in the high-energy portion of the spectrum to the total recorded pulses. For a single radionuclide, the ratio of cpm in the high-energy range of the spectrum to total cpm is proportional to the efficiency of counting. This method of quench correction is very effective for single-labeled samples, but is not suitable for correction of counts from dual-labeled samples.

In practice, two counting channels are selected. Let channel 1 encompass the entire range of possible pulse heights for the radionuclide. Channel 2 constitutes the range of pulse heights from some intermediate value (LL) to the maximum pulse height. Modern liquid scintillation counters that are equipped with programming automatically select appropriate channels for specific radioisotopes. A set of sealed quenched standards of known dpm is counted to yield channel 1 cpm and the SCR for each standard. Instead of sealed standards, quenched standards can be prepared by the operator. The quenching agent need not be the same agent responsible for quenching the experimental samples. To prepare quenched standards, equal activities of nuclide are added to each of a number of vials containing equal amounts of scintillation cocktail. Progressively increasing amounts of a quenching agent such as carbon tetrachloride are then added to the vials. A quench curve is prepared by calculating fractional efficiency for each standard (Equation 13) and plotting fractional efficiency against SCR.

To convert cpm to dpm for a sample, the cpm for channel 1 and the SCR are recorded. Fractional efficiency of counting is determined from the quench curve. If the background radiation is significant, then the average background cpm (determined from unlabeled samples) are subtracted from the total channel 1 cpm and the remaining cpm are divided by the fractional efficiency to obtain dpm.

The energy level that establishes an UL or LL for a channel is called a discriminator setting. The choice of discriminator that establishes an LL for channel 2 depends on the expected extent of quenching.\(^7\) If the LL is set too high, then all of the SCR measurements will be near zero for moderate to severely quenched samples. On the other hand, too low a limit attenuates the relationship for slightly quenched samples, affecting the accuracy of the dpm determination. In Figure 9, distributions of pulse heights and a set of discriminator settings are depicted for moderately quenched and severely quenched samples. For moderately quenched samples this choice of discriminator setting is appropriate. Decreasing the LL for channel 2 would lower the sensitivity of changes in SCR to changes in counting efficiency. However, with this LL, SCR values for severely quenched samples would all be zero despite differences in the degree of quenching of individual samples. A lower discriminator setting, giving channel 2 a broader range, would be required for such samples.

In addition to the problem of adjusting discriminator settings to compensate for differences in quench range, quench correction by SCR can require long counting times for samples with low specific activity. The statistical accuracy of the SCR depends on the accuracy of channel 2.
counts, a number that is smaller and therefore less reliable than total counts.

4.3.3.3 Quench Correction Using an External Standard
An external standard consists of a high-energy γ-source that can be brought in proximity to the sample vial and separated from the vial by shielding when the sample is actually counted. A fraction of the γ-photons that strike the vial and contents undergo Compton scattering, and the Compton electrons subsequently produced can excite solvent molecules in an identical manner to β-particles emitted by the internal source.

The earliest form of quench correction using an external γ-photon source involved measuring the counts in a specific pulse height range (channel).\(^{(7)}\) It was called the external standard counts per minute (ESCPM) method. To use this method, quenched standards are prepared as for the SCR method and a series of standards is counted to obtain counting efficiency and the external standard count. Correction for any counts from the samples themselves that overlap the external standard window must be made. As for SCR, a standard curve of efficiency versus ESCPM is prepared and efficiencies of counting individual samples are determined from the curve. Also as with SCR the choice of discriminator settings depends on the level of quenching expected. Too high a discriminator setting for severely quenched samples results in values of zero for the ESCPM of most samples, while too low a setting for moderately quenched samples results in too great a loss of resolution.

The ESCPM method is seldom used at present because of serious limitations on preparation of the samples. The number of scattered electrons, and therefore the results for a single data point, depends on the position of the γ-source relative to the sample as well as the volume and electron density of the sample. Error accumulates as a result of preparation of samples containing different materials and amounts of material.

The external standard channels ratio (ESCR) method is similar to the SCR method in that it yields a ratio rather than a direct count. The effects of varying source position, sample volume, and sample density cancel out, since they all equally affect counts in both channels. The choice of discriminator settings again depends on the necessary quench range. As with the ESCPM, sample counts must be subtracted from external standard counts when the sample itself contributes to counts in either of the channels selected. As with the previous methods, dpm for samples is determined by plotting counting efficiency versus the ESCR and dividing measured cpm by the fractional efficiency corresponding to the ESCR for each sample.

A very effective method of quench monitoring that appears to be superior to either of the previous methods using an external γ-ray source is measurement of the pulse height corresponding to the Compton edge of the scattered electrons.\(^{(7)}\) Quenching affects the pulse height distribution in response to Compton scattering as it affects the pulse height distribution for a β-particle emitter; that is, pulse heights produced when photons are detected by the PMTs are reduced by quenching. For practical purposes counting efficiency is plotted versus one-half the value of the pulse height of the Compton edge.

Beckman Instruments, Inc., starting with its LS 8000 series liquid scintillation counters, included the option to determine a number called an “H#” for quenched samples. The instruments introduce the external standard and rapidly take counts in a series of narrow channels to determine the pulse height corresponding to the inflection point of the Compton distribution for the sample. The pulse height positions of a typical set of quenched and unquenched samples are illustrated in Figure 10. The H# is the difference in measured pulse heights between the inflection points of the quenched sample and an unquenched sample. In Figure 10 the H# would be \(780 - 513 = 267\). To set up a standard curve, H# values are determined for quenched standards and fractional efficiency is plotted versus H#.

4.3.4 Example of Single Label Counting

4.3.4.1 Example of Quench Correction for Carbon-14 Using the Sample Channels Ratio Method
All data were obtained using a Beckman LS 3801 liquid scintillation counter (Beckman Instruments, Inc., Fullerton, CA, USA). Progressively quenched standards, each containing 51 000 dpm carbon-14 activity, were counted in two channels. Discriminator settings for channel 1 were: LL, 0; UL, 655. This range includes pulse heights corresponding to β-particle energies from zero to \(E_{\text{max}}\) for carbon-14 (UL of 655 includes signals from β-particles with energy 51 000 dpm carbon-14 activity, were counted in two channels. Discriminator settings for channel 1 were: LL, 0; UL, 655. This range includes pulse heights corresponding to β-particle energies from zero to \(E_{\text{max}}\) for carbon-14 (UL of 655 includes signals from β-particles with energy

Figure 10 Shift in pulse height of the inflection point of the Compton edge for quenched and unquenched samples.
up to 156 keV). An LL of 400 was selected for channel 2, with a UL of 655, and both channel 1 counts and SCR were determined. Similar data were collected with the channel 2 LLs set at 300 and 500 respectively (Figure 11). The scale is arbitrary. To accomplish quench correction it is not necessary to know the energy level that corresponds to a particular LL. Fractional efficiencies were calculated from channel 1 cpm using Equation (14).

\[
dpm = \frac{\text{channel 1 cpm}}{\text{fractional efficiency}}
\]

Equation (14)

LL values of 300 and 500 were clearly unacceptable. The former reduced the accuracy of the curve by attenuating the possible range of SCR values. With the latter setting, the efficiency of counting moderate to severe samples could not be distinguished. With an LL of 400 there is still some loss of accuracy at the low end of the curve, so LL = 375 was finally selected (Figure 12).

An experimental sample yielded an SCR of 0.34 and channel 1 cpm of 17250. From Figure 12, the fractional efficiency corresponding to an SCR of 0.34 is 0.82. Activity in the sample was determined by dividing 17250 by 0.82 to give 21036 dpm.

4.3.5 Dual Label Counting

If there is considerable disparity in \( E_{\text{max}} \) between two nuclides A and B, then reliable determinations of activity can be obtained for both emitters, even when they are included in the same sample. For measurement of activity in such dual-labeled samples, the ULs and LLs for channels 1 and 2 should be set as illustrated in Figure 13. Note that the discriminator settings are chosen so that the channels do not overlap, which was not the case for single-labeled samples.

Channel 2 returns only those counts due to the presence of the higher energy emitter, nuclide B. Channel 1 includes counts from nuclides A and B. The cpm due to nuclide B can be determined by carrying out the following two steps. First, a sample containing a known amount of B is counted and the ratio \( R \) of channel 2 cpm to known dpm for B is determined from the count. Second, the experimental samples are counted, and for each sample the channel 2 cpm are divided by \( R \) to get cpm for nuclide B.

The cpm recorded in channel 1 include all cpm due to source A as well as “spillover” cpm due to source B. The spillover cpm must be calculated and subtracted from the channel 1 cpm to determine what proportion of the count rate is due to source A. Spillover is determined by subtracting channel 2 cpm from the total cpm value for source B that was calculated previously. Subtracting spillover cpm from channel 1 cpm gives the cpm due to source A. If quenching is not significant, this method suffices as an estimate of dpm for both emitters. With significant quenching, an external standard can be used to estimate dpm (see section 4.3.5.1).
All of the manipulations described here are subject to error propagation, and this should be taken into account (section 3.3). The proportion of the lower energy nuclide should be high so that spillover counts are a fairly small fraction of channel 1 counts (see section 4.3.5.1).

4.3.5.1 Example of Counting Dual-labeled Samples Containing Tritium and Carbon-14

Figures 14 and 15 are quench curves that were developed using the H# method for single-labeled quenched standards containing carbon-14 and tritium, respectively. Channels were set up as illustrated in Figure 13. Fractional efficiency for each nuclide was calculated by dividing cpm by known dpm in the sample. This applies to carbon-14 as well as tritium, even though “spillover” counts from carbon-14 into channel 1 were not counted.

A third plot (Figure 16) is also necessary, namely a plot of the ratio of channel 1 to channel 2 counts versus H# for the quenched carbon-14 standards. This plot is used to estimate “spillover” counts of carbon-14 into the tritium channel.

To obtain dpm for carbon-14 in a mixed sample, H# is used with the quench curve of Figure 14 to obtain the fractional efficiency for the sample; dpm are then estimated using Equation (15).

\[
dpm^{\text{14C}} = \frac{\text{channel 2 cpm}}{\text{fractional efficiency}}
\]  

Estimation of the contribution of tritium requires the use of the curves in Figures 15 and 16. To determine spillover cpm (not dpm) of carbon-14 into the tritium channel, the ratio \( R \) of channel 1 to channel 2 counts is determined from the H# of the unknown using the curve in Figure 15. Spillover cpm are then given by Equation (16).

\[
\text{spillover cpm} = \frac{\text{channel 2 cpm}}{R}
\]  

Spillover cpm are subtracted from channel 1 cpm to get cpm due solely to the tritium label, and then the quench curve in Figure 15 is used to estimate dpm for tritium.

A dual-labeled sample gave channel 1 counts of 44 583 and channel 2 counts of 23 444, with H# = 150. From Figures 14 and 15 the fractional efficiencies are 0.88.
for carbon-14 and 0.07 for tritium. Figure 16 gives a value for $R$ of 0.60. From Equation (15) the total dpm contributed by carbon-14 are $23,444/0.88 = 26,640$. From Equation (16) the spillover cpm = $(23,444)(0.60) = 14,066$. Subtracting spillover counts from channel 1 cpm yields $44,583 – 14,066 = 30,517$ cpm for tritium. Correcting for quenching, tritium dpm are given by $30,517/0.07 = 435,957$, which should be reported as $436,000$ dpm with rounding to significant digits.

Note that in this example it was not necessary to subtract background radiation, which averaged 20 cpm per sample. For high count rate samples, background radiation can be ignored. Background radiation must be subtracted for samples with low activity and, to the extent that background radiation adds experimental error, confidence in the accuracy of the result is reduced.

4.4 Organic Crystal Detectors

For detection of high-energy $\beta$-particle emitters, organic crystals provide effective detectors. The most commonly used materials are anthracene ($C_{14}H_{10}$), trans-stilbene ($C_{14}H_{12}$), and quaterphenyl ($C_{24}H_{18}$). The source is brought into a cavity in the crystal, and $\beta$-radiation from the source causes excitation and de-excitation of the electrons in the benzene ring structures. Excited electrons lose some excess energy through thermal interactions until they reach a minimal energy in the excited state, from which they de-excite with emission of a photon. The absorption spectra and emission spectra do not match, from which they de-excite with emission of a photon. The extent that background radiation adds experimental error, confidence in the accuracy of the result is reduced.

5.1 Ionization Chambers

When $\beta$-particles pass through a gas, leaving trails of ion pairs, the numbers of positive ions and ejected electrons produced are proportional to the initial kinetic energy of the particle. When an electric field is applied to the gas, the ions are attracted to the electrodes and an electric current is produced. A simple ionization chamber might consist, for example, of a cylindrical volume of gas with the outer wall serving as the cathode and an inner wire running the length of the cylinder axis to serve as the anode. Each ionizing event produces a measurable discrete current pulse of specific height.

If the voltage drop between electrodes is small, the ion pairs recombine before electrons can reach the anode, and most of the signal is lost. In a voltage range of approximately 40–200 V cm$^{-1}$ nearly all electrons reach the anode, and the instrument reaches saturation. This voltage range allows effective detection of $\alpha$-radiation. $\alpha$-Particles remain of their initial kinetic energy following an interaction with a gas molecule, thus many ion pairs are produced per event, and the current that is produced is relatively large. It is nearly impossible to detect $\beta$-particles in this range, however. The mass of an electron is so small that $\beta$-particles quickly lose kinetic energy in a gas and the current pulses produced by $\beta$-particle emissions are nearly undetectable.

5.2 Proportional Counters

A proportional counter operates on a principle similar to that of an ionization chamber, but the electric field is stronger. As electrons are accelerated toward the anode they collide with other molecules with sufficient energy to produce secondary fast electrons, amplifying the signal by a factor of $10^3–10^5$ depending on voltage and field strength. This proportional range is approximately 200–800 V cm$^{-1}$. Proportional counters yield information that can be analyzed for pulse height distribution as well as total counts. Dead times for proportional counters are of the order of a few microseconds. Thus when count rates are less than 10 kBq or so (1 kBq = $10^3$ dps), the probability of an event going undetected is negligible. Dead time is a concern when count rates approach 100 kBq.

Solid or gaseous samples can be introduced into the chamber or gas can be passed through the chamber, in which case the instrument is called a flow counter. Because self-absorption is a problem with solid samples, solids should be introduced as thin films. This can be accomplished by electroplating or vapor coating, or if the material is soluble by applying a film of solution.
to a surface and allowing the solvent to evaporate. Windowless proportional counters are quite acceptable for counting low-energy $\beta$-particle emissions, especially carbon-14 and tritium. The dimensions of proportional counters limit the degree to which energy from a $\beta$-particle is dissipated within the sensitive volume. The number of ion pairs produced from a high-energy particle is proportional to only a small fraction of the energy, the rest being lost through collision with the wall opposite the sample. Thus proportional counters can be used for quantitation of activity of higher energy emitters, but energy discrimination with such emitters is not possible.

5.3 Geiger–Müller Counters

When the voltage drop between electrodes in a gas-filled counter is of the order of kilovolts, a single ionization event leads to an avalanche of photon production and secondary ionizations that results in an easily measurable pulse of several volts. The pulse height is independent of the initial kinetic energy of the radiation. Gas-filled devices that operate in this range are called Geiger–Müller counters, and are usually filled with argon or helium. Since the signal is the same regardless of the intensity of the radiation, Geiger–Müller counters yield only counts of activity and cannot be used for energy resolution. Electric field strengths for Geiger–Müller counters can range from 900 to 1400 V cm$^{-1}$, depending on the geometry of the chamber, type of fill gas, etc. In the high electrical field strength of a Geiger–Müller counter, a large number of positive ions are formed from the filling gas as well as electrons. When the positive ions reach the cathode after a typical dead time of 100–500 µs, they combine with electrons at the cathode surface. Frequently this process results in the liberation of an electron from the surface which in turn can trigger a full discharge. Such recycling can result in a continuous output of pulses from one decay event. The problem is solved by adding a second gas, a quench gas, to the filling gas. Quench gases include ethyl alcohol and ethyl formate, which are ultimately consumable and limit the useful lifetime of the chamber. Alternative quench gases include halogen gases such as chlorine or bromine. A suitable quench gas has a lower ionization energy than the filling gas, so that the filling gas tends to transfer positive charge to the quench gas as the charge drifts toward the cathode. Thus, the positive ions that eventually reach the cathode are derived from the quench gas. When positive ions from the quench gas recombine with electrons at the cathode, the energy of recombination is dissipated by dissociation or excitation of quench gas molecules, not filling gas molecules. The proportion of quench gas to filling gas molecules is small, so the event “dies out” rather than producing a full discharge. The free energies of dissociation and recombination of preferred quench gases are relatively small, and such gases strongly absorb photons that are liberated in the process, further preventing secondary discharges.

Geiger–Müller counters are fairly simple devices and are suitable for high-energy $\beta$-particle detection when only a count rate is needed, and for low-energy emissions (except for tritium) if a suitable window is selected. Because such counters are usually equipped with a window that absorbs much of the energy from fast electrons, they are of limited value for low-energy $\beta$-particle determination.

6 SOLID-STATE DETECTORS

The density of a solid is approximately 1000 times greater than that of a gas, therefore many more information carriers can be packed into a relatively small volume. This gives the advantage of relative compactness. A single ionization can produce many more carriers in semiconductor material than in other media, thus detectors utilizing semiconductors are capable of greater energy resolution than any other type of detector. A number of materials are used, but for $\beta$-particle determination silicon has been the material of choice.

The basic operating principles of solid-state detectors are similar to those of gas-filled counters, but the gas is replaced by a solid consisting of a semiconductor material. Typical semiconductor material has a resistivity intermediate between highly conductive metals and insulating material. Most of the electrons in silicon, for example, are valence electrons—that is, they are associated with specific atoms. When the material is sandwiched between two electrodes and a voltage is applied across the material, very little current can be produced. However, when an electron in semiconductor material is given a discrete energy by ionizing radiation, it is moved to an energy level that leaves it independent of any individual atom and leaves a vacancy called a hole. Thus ionizing radiation produces electron–hole pairs which both move toward an anode, thus conducting electricity and producing a pulse. Ionizing radiation of varying energies produces a continuum of pulses, permitting spectral analysis.

The addition of impurities to semiconductor material can result in a lowering of the energy required to produce an electron–hole pair. For example, phosphorus has five valence electrons and indium has three. Incorporation of a small amount of phosphorus into a silicon chip gives the material an excess of negative charge and considerably lowers the energy needed to raise a valence electron to the conduction band. Such material is called n-type, for negative. Indium contributes an excess of holes, which can be treated as an excess of positive charge, producing...
p-type material. When p-type material is coated with n-type material, electrons move from the n-type material to the p-type material and combine with holes to produce a region in which there are no charge carriers. This surface barrier is of very high resistance, permitting a high voltage to be placed across the device. The reverse bias resulting from placement of a positive electrode on the n-type side and a negative electrode on the p-type side increases the zone of depletion of charge carriers. When the n-type surface is exposed to ionizing radiation, current pulses are produced as electrons are excited to the conduction band.\(^7\)

Silicon barrier detectors are especially useful for charged particle (\(\alpha\) or \(\beta\)) spectroscopy.

7 VISUAL IMAGING

Visual imaging methods are used in tracer experiments for detection of labeled structures or molecules. While such methods are not used for direct quantitation of \(\beta\)-activity, they deserve mention here because of their importance in research, especially in the life sciences. In addition, films are used in dosimetry, most commonly in the form of a film badge. A film badge is sensitive to radiation that can penetrate air, such as \(\gamma\)- and high-energy \(\beta\)-particle emissions. Incident radiation forms silver ions in the grains of a film or emulsion, recording the position of impact just as such photographic materials record the impact of photons from visible light.

Common applications in research include autoradiography, in which a film or emulsion is exposed to material containing labeled substances. The locations of labeled structures or molecules can be determined by superimposing the photographic image over the image of the material itself. Examples are thin sections of labeled tissues, or electrophoretic gels containing labeled macromolecules. \(\beta\)-Particle emitters are also used to label antibodies and other molecules that bind specific sites in such materials, allowing identification of structures and macromolecules by visual imaging. A large body of literature under the subject of autoradiography is available in this area.

High-resolution γ-spectrometry is a nondestructive assay method that gives low detection limits for many radioactive nuclides. γ-Spectrometers use an electric field to collect the free charge carriers, electrons and holes, in a semiconductor detector. Modern detectors are based on high-purity germanium (HPGe). The material properties of germanium containing extremely low concentrations of impurity atoms are excellent at low temperature (77 K) for creating and collecting charges in the sensitive region of the detector. The major components of the spectrometer are the detector, cooling system, shielding system, signal processing unit, and analysis software. The charge created at the detector is directly proportional to the energy deposited in the detector by the radiation. The weak charge pulse is transformed, shaped and amplified to a voltage pulse, which is then converted to digital form. A multichannel analyzer (MCA) collects and stores the spectrum, which comprises counts partitioned among different channels according to energy dissipated in the detector. The spectrum contains peaks that can be unequivocally associated with certain radionuclides. Peak areas are proportional to the activity of the nuclide. Meticulous calibrations are required to operate the instrument properly. Software plays a major role in the analysis of the spectra, and interactive human work and artificial intelligence, i.e. an expert system, are needed to handle complex cases. Stable elements can be analyzed through neutron activation and subsequent γ-spectrometric determination. γ-Spectrometry is not a sensitive method for radionuclides that have a long half-life (≫30 years).

1 INTRODUCTION

Nondestructive analyses of material structure and composition are fascinating techniques that have
applications in many human activities. X-ray fluorescence, for example, is a widely used method to characterize impurity concentrations within a sample matrix. The sample atoms are excited by photons from an X-ray generator or from a radioactive source. Prompt X-rays are then emitted in the rearrangement of the K and L shells. These X-rays, characteristic to each element and usually of low energy (<30 keV), are detected with a spectrometer. Similarly, neutron activation and subsequent γ-spectrometry may reveal the presence of other impurity atoms in a sample matrix. Furthermore, the environment and the samples collected from the environment may contain trace amounts of man-made radionuclides or natural radionuclides that can be detected, identified and quantified directly with a high-resolution γ-spectrometer. The energy range of interest extends up to 3 MeV (10 MeV in special applications). The analytical capability of the γ-spectrometry is often superior to other assay methods.

Ionizing radiation is detected through its various interactions with matter. The atoms and the molecules of the absorbing medium are excited or ionized. The ionization events result in the creation of free charge carriers that drift in an electric field. The de-excitation of the excited and ionized atoms may also result in the emission of luminescent photons. Luminescence is used in scintillation detectors, whereas collection of free charge carriers is the key operational principle of gas-filled detectors, such as the ionization chamber and proportional counter, and of solid-state detectors based on semiconductors.

In a semiconductor detector, a photon produces an electrical signal (pulse) of size proportional to the energy deposited in the detector, over a wide energy range (0.1 keV to 10 MeV). In a γ-spectrum, these pulses are detected as narrow peaks at the characteristic energy of the emitting nuclide.

γ-Spectrometry is a discipline or domain in which many dimensions have to be taken into account. The true interpretation of a multiplex spectrum originating from multine γ-emitters requires understanding of the phenomena involved in the detection process. The complexity of the measurement and the analysis is very often underestimated in practice and, consequently, invalid procedures are implemented that distort the identification results and the activity or concentration calculations.

The analyst must understand the basic physics behind the γ-spectrum and be able to select and set up the instruments for best performance in a cost-efficient manner. Of particular importance is the energy resolution of the spectrometer. High resolution in optimized counting geometry paves the way for low detection limits, is an indication of good quality of the measurement, and is an essential prerequisite for nuclide identification and quantification in complex spectra.

2 SEMICONDUCTOR DETECTORS

The sharply defined atomic electron energy levels are broadened into bands of energy states in a crystal. The outer electrons of the atoms are bound in an energy band, known as the valence band. The higher energy state, the conduction band, is separated from the valence band by an energy gap. An electron can be transferred from the valence band to the conduction band under the influence of external or internal (thermal) energy greater than the energy gap. Within the conduction band electrons can move freely. Silicon and germanium have most favorable material properties for radiation detection (Table 1).

Semiconductor research became intensive in the 1950s. It was soon realized that detectors made of germanium always need cooling, whereas silicon detectors could also

³ T = 300 K.
be operated in room temperature (owing to different band gaps). The early detectors were intended for charged particle measurements because the achievable sensitive thickness was only a few hundred micrometers, which was sufficient to absorb energy from particles but not from the more penetrating photons.

In the early 1960s silicon detectors were manufactured using lithium diffusion and drift techniques for the compensation of material impurities. Silicon detectors several millimeters thick could be produced, and were successfully applied to X-ray spectrometry. However, the small photoelectric absorption cross-section because of the low atomic number makes silicon ineffective for $\gamma$-spectrometry at high energies (Figure 1).

The impurity compensation techniques using lithium atoms was utilized in 1962 by Freck and Wakefield to produce a detector, known as the lithium-drifted germanium (Ge(Li)) detector. The first detectors were designed for planar geometry but soon the coaxial shape was adopted to construct large-volume Ge(Li) detectors for $\gamma$-spectrometry. These detectors provided very high-energy resolution, and revolutionized the analysis of $\gamma$-emitting radionuclides. Sample preparation became simple because radiochemical purification was no longer needed before sample counting. One drawback was that the Ge(Li) detectors had to be kept at low temperatures all the time in order to prevent the high-mobility Li atoms drifting away and damaging the detector. Ge(Li) detectors introduced the age of high-resolution $\gamma$-spectrometry, but their production ceased after the development of ultra-HPGe.

In the early 1970s germanium was purified to a level that made it possible to construct detectors without lithium compensation. Nowadays germanium crystals with extremely low impurity concentrations ($10^{15}$–$10^{16}$ atoms per m$^3$) can be produced. In 1998 detector-grade germanium was manufactured by only three companies (EG&G Instruments USA, Tennelec, USA, and Hoboken, Belgium). Unlike the Ge(Li) detector, the HPGe detector can be stored and manipulated at room temperature, although for measurement it too must be cooled using either liquid nitrogen ($77$ K) or an electrical system.

### 2.1 Photon Interaction with Matter

The photoelectric effect, Compton scattering, and pair production are the major mechanisms through which energetic photons interact with matter. By these processes the energy of the incident photons is transferred to the kinetic energy of electrons, which in turn produce charge carriers, free electrons and positively charged holes, in the detector medium. Each mode of interaction produces different effects within the resulting $\gamma$-spectrum.

In photoelectric absorption, the incident photon of energy $E$ interacts with a bound electron. The entire energy of the photon is absorbed, and an electron (K or L) is ejected with energy $E - E_B$, where $E_B$ is the binding energy of the electron. However, $E_B$ is quickly transferred to a characteristic X-ray as a result of a subsequent transition between the energy levels of the electrons. The deposition of the entire energy of the photon in the detector produces a prominent peak in the spectrum, known as the full-energy peak, photo-peak or $\gamma$-peak. When the interaction occurs near the detector surface, the characteristic X-ray may escape from the detector. In a $\gamma$-spectrum acquired with a germanium detector, a small peak may sometimes be found 10 keV below the full-energy peak (Figure 1).

The photoelectric absorption cross-section is proportional to $Z^2/E^{3.5}$ (or to $Z^{2.5}/E^3$), where $Z$ is the atomic number.$^{1,5}$ Therefore, heavy atoms absorb $\gamma$-radiation much more effectively than light atoms. An ideal detector...
material has a high Z value. This is why silicon is not well suited for γ-spectrometry at high energies.

The incident photon may also be scattered by an electron. The process is known as Compton scattering. The initial photon energy is then shared by the electron and the scattered photon. This secondary photon may be absorbed in a subsequent photoelectric event, may be further scattered, or may leave the detector without further interaction. In the last case only the energy transferred to the electron is absorbed. Because of variability of energy transfer in scattering events, Compton scattering produces a smooth baseline continuum in the γ-spectrum. This continuum increases detection limits of radionuclides (see section 6.5). Compton scattering is the dominant interaction process in germanium between energies 150 keV and 8 MeV (Figure 1).

In pair production, the energy of the incident photon must exceed twice the rest mass energy of an electron (2 × 511 keV). The incident photon is completely absorbed and an electron–positron pair is created in the electric field of the nucleus of the absorbing material. Pair production may occur also in the field of an electron, but the probability is low. The electron and the positron transfer their kinetic energy to the medium. Annihilation of the positron in germanium produces two γ-rays that must also be absorbed in the detector to produce a full-energy peak. However, one or both of these photons may escape the detector.

When both photons created in the annihilation leave the detector without interaction, a double escape peak may be found in a γ-spectrum at energy of 1.022 MeV below the photo-peak. If only one of the two photons leaves the detector, a single escape peak may be produced at energy of 511 keV below the photo-peak. However, the single escape peak and the 511 keV annihilation peak are broader than the photo-peaks nearby because of the Doppler effect. At the point of annihilation, neither the electron nor the positron is at complete rest. The conservation of energy and momentum implies that the photons have slightly different energies. The degree of Doppler broadening depends on the annihilation environment, i.e. on the detector material. The resulting annihilation and single escape peaks are typically 1–2 keV broader than the photo-peaks at the same energies.

2.2 Production of Electrons and Holes

In a perfect semiconductor there are no electron energy levels within the band gap (Figure 2). Therefore, to raise a bound electron from the valence band to the conduction band a minimum energy, $E_g$, the energy difference between the top of the valence band and the bottom of the conduction band, is needed. Thermal excitation or radiation interacting with semiconductor material can break the bonds of the electrons. For each free electron there is a missing electron or hole in the valence band. The electrons in the conduction band and the holes in the valence band are mobile in the electric field.

The interaction of photons with semiconductor medium is a complicated cascade. Not all of the energy of the primary photon is consumed for the ionization of the medium. Some of the energy of the incident photon is transferred to the lattice as phonons, and the average energy $W$ needed to produce an electron-hole pair is therefore larger than the band-gap energy $E_g$ (Table 1). The non-ionizing processes dominate only at very low energies, and, consequently, $W$ does not depend on the energy or type of the radiation.

Absorption of energy $E$ produces $n$ electron–hole pairs, on average, in the sensitive region of the detector as illustrated in Equation (1):

$$n = \frac{E}{W}$$

As a result of energy transfer from ionizing radiation to the semiconductor medium, tightly bound electrons of the atoms in the lattice may be raised to energy levels well above the bottom of the conduction band. The energies of such excited electrons and the embedded holes are transferred to other electrons and holes through a series of interactions. Finally, the holes are at the top of the valence band and the electrons at the bottom of the conduction band. Eventually the excited electrons in the conduction band return to the valence band and then the number of electron–hole pairs is again dominated by thermal
excitation. In an electric field, however, the electrons and holes migrate according to the field direction.

The number of electron–hole pairs formed in the detector medium plays a major role in detector resolution. If their amount would follow Poissonian statistics, the standard deviation would be (Equation 2)

$$\sigma_{n,\text{Poisson}} = \sqrt{n} = \sqrt{\frac{E}{W}}$$

The energy uncertainty, i.e. the standard deviation of the full energy absorption would then be (Equation 3)

$$\sigma_E = W\sigma_{n,\text{Poisson}} = \sqrt{WE}$$

In reality, however, the resolution of the detector is much better than the prediction of Equation (3). Simple Poissonian statistics do not describe the formation of electron–hole pairs. A correction factor, known as the Fano factor, $F$, must be introduced, as illustrated in Equations (4) and (5):

$$\sigma_n^2 = F\sigma_{n,\text{Poisson}}^2 = F\frac{E}{W}$$

Therefore,

$$\sigma_E = W\sigma_n = \sqrt{FWE}$$

If all of the energy transferred to the semiconductor medium went into creating electron–hole pairs, there would be no statistical fluctuation, and the Fano factor would be zero. On the other hand, if only a small fraction of the absorbed energy were used to produce electron–hole pairs, the fluctuations would be truly random, and the Poissonian statistics would be valid. For the semiconductors, the real situation is between these two extremes. The exact value of the Fano factor is not known, and the experimental values vary considerably (Table 1). The Fano factor seems to be somewhat smaller for germanium than for silicon; in addition, the $W$ values are smaller for germanium (Table 1). Thus, Equation (5) predicts that the germanium detectors have slightly better energy resolution than the silicon detectors.

In a scintillation counter, such as the sodium iodide detector, the energy of the primary photon is transferred to light photons, and these photons in turn produce photoelectrons at the cathode of a photomultiplier. However, the efficiency of the photoelectron production is low (about 10%) in this random multistep process and, consequently, the Poissonian statistics are valid, i.e. $F = 1$. Furthermore, production of a photoelectron at the photocathode requires energy of about 170 eV. Thus, the peak widths of the spectra acquired with a NaI detector are very large compared with the high resolution of the germanium detector. The NaI peak widths are 20–30 times greater than HPGe peak widths, as calculated from Equation (5) using Fano factors of 0.06–0.12 for germanium. In practice, depending on the type of detectors and quality of the electronics, the resolution difference may be as large as a factor of 50.

The overall resolution of the detector is determined by charge production, uncertainty of charge collection, and noise of electronic devices (section 3).\(^{(6,7)}\)

2.3 Properties of Semiconductors

Thermally generated free electrons and holes give rise to electrical conduction in the crystal. This intrinsic semiconduction is characterized by equal concentration of electrons and holes. In Equation (6) the concentration $n_i$ of electrons and holes depends on temperature as\(^{(8)}\)

$$n_i = CT^{3/2}e^{-E_i/2kT}$$

where $C$ is a factor independent of temperature $T$ and $k$ is the Bolzmann constant (1.3805 $\times$ $10^{-23}$ J K$^{-1}$). Values of $n_i$ can be derived from conductivity measurements.

At room temperature, $n_i$ is 1.5 $\times$ $10^{16}$ m$^{-3}$ for silicon and 2.4 $\times$ $10^{13}$ m$^{-3}$ for germanium.\(^{(8)}\)

The intrinsic carrier concentration determines the lower limit of the leakage current in a detector. To minimize leakage, i.e. to reduce the number of electrons in the conduction band, the detector has to be cooled to a low temperature. Cooling is necessary for all germanium detectors and for high-resolution silicon X-ray detectors.

2.3.1 Impurity Doping

Adding impurity atoms of the fifth or third group of the periodic table increases electrical conductivity of an intrinsic semiconductor. Phosphorus or arsenic atoms, for example, need only four of their five valence electrons to complete covalent bonds to Ge or Si atoms. The extra electron is very loosely bound, has an energy level near the conduction band, and is easily moved to the conduction band, thus increasing the conductivity of the material. Impurity atoms that donate electrons to the conduction band are known as donors. Germanium with such impurity is said to be of n-type (negative donor impurities). Similarly, some atoms, such as boron, accept electrons from the valence band, leaving behind a hole that can move through the crystal. These impurity atoms are known as acceptors. Germanium with such impurity is said to be of p-type (positive acceptor impurities).

A real crystal contains both donor and acceptor impurities. These impurity atoms tend to neutralize each other, i.e. the electrons of the donors fall into the acceptor levels and no free charge carriers are formed. The properties of the semiconductor depend on the type of impurity that is present in excess. Let $N_D$
and \( N_A \) be the donor and acceptor concentrations. The net concentration, \( N_D - N_A \) (n-type) or \( N_A - N_D \) (p-type), and the dominating impurity element determine the quality of the crystal. The material is said to be compensated, if \( N_D = N_A \). In practice a small imbalance exists between donor and acceptor concentrations.

In an n-type crystal the electron concentration, \( n_e \), is increased in the conduction band. Because of this, recombination disturbs the equilibrium amounts of electrons and holes. As a result, the hole concentration, \( n_h \), is lower than the charge carrier concentration, \( n_c \), of the intrinsic material, see Equation (7), in such a way that

\[
n_e n_h = n_i^2
\]  

(7)

If a region is heavily doped with donors, the number of holes is reduced to a negligible level. Thus, in an n-type material the electrical conductivity is determined by electrons. Similarly, the motion of holes dominates conductivity in a p-type material.

The heavily doped layers are called as n+ or p+ layers. The concentration of the doping atoms can be as high as \( 10^{24} \) m\(^{-3} \). These layers provide blocking contacts that are necessary for the functioning of a detector (see section 2.4). Evaporation and diffusion or ion bombardment are utilized for the manufacture of the blocking contacts in commercial detectors.

2.3.2 Charge Traps

Charge trapping and recombination are the result of impurities or defects in the crystal. Impurities, such as zinc and cadmium, within the lattice have energy levels deep in the band gap. These impurities may trap charge carriers temporarily, thus preventing them from contributing to the electric signal of the preamplifier. The trapping efficiency is proportional to the Boltzmann factor, \( \exp(-E/kT) \), where \( T \) is the operating temperature and \( E \) the binding energy of the trap. At low temperatures the trapping is more enhanced than at room temperature. Some impurities can trap both electrons and holes, which will then annihilate. This process is often more probable than direct recombination through the band gap. Structural defects of the lattice can also trap charge carriers.

The charge-carrier life time, \( \tau \), is a measure of the quality of the crystal. In a good crystal \( \tau \) is of the order of 0.1–1 ms. Detector manufacturing processes may shorten carrier life time but it is still sufficient for the proper operation of the detector because the charge collection time is below 1 \( \mu \)s (see section 2.5).

2.3.3 Motion of Charge Carriers

In an electric field, electrons and holes move in opposite directions in the crystal, with drift velocities directly proportional to the electric field strength. The constant of proportionality is called “mobility”. The mobility of the electrons, \( \mu_e \), is of the same order of magnitude as the mobility of the holes, \( \mu_h \). Both types of charge carrier have therefore a significant influence on the signal of the detector. The lower the temperature the higher the mobility (\( T^{-3/2} \)). Therefore, cooling a germanium detector not only reduces leakage current but also improves the efficiency of the charge collection.

Resistivity, \( \rho_p \), of a p-type semiconductor depends on mobility of the holes and on concentration, \( N_A \), of the acceptor material\(^{\text{i,5}} \) as illustrated in Equation (8):

\[
\rho_p = \frac{1}{\mu_h eN_A}
\]  

(8)

Similarly, the mobility of electrons and the donor concentration, \( N_D \), dominate the resistivity in an n-type crystal.

Since the quality of a crystal depends on mobility and carrier life time, a quantity \( \mu \tau \) is sometimes used as a quality index. Assuming a life time of 20 \( \mu \)s for the charge carriers in a germanium detector, the product \( \mu \tau \) would be about \( 7.2 \times 10^{-5} \) m\(^2\) V\(^{-1} \) for the electrons and \( 8.4 \times 10^{-5} \) m\(^2\) V\(^{-1} \) for the holes (Table 1). In other semiconductor materials (section 9), except silicon, the product \( \mu \tau \) is several orders of magnitude lower than for germanium.

2.4 p–n Junction

To detect the small transient current produced by the energy absorbed in the detector, the background or the leakage current must be negligible (hence conductors are not suitable for radiation detection). Leakage is small in insulators but they have other problems, such as large \( W \), small \( \mu \), and charge losses through trapping. These problems are avoided in the semiconductors. The leakage current is extremely low at low temperatures \( (10^{-9} \) to \( 10^{-12} \) A at 77 K)\(^{\text{i,9}} \). However, a bias voltage applied to a pure semiconductor material would produce a leakage current several orders of magnitude larger than the peak current (a few microamperes) caused by the absorption of photons and subsequent motion of electrons and holes. Consider, for example, a high-purity silicon wafer with resistivity of 50 000 \( \Omega \) cm (see intrinsic material in Table 1), thickness of 0.1 cm and surface area of 1 cm\(^2 \). A small potential difference of 50 V across the wafer would produce a current of 10 mA\(^{\text{j,7}} \). Therefore, silicon and germanium alone cannot be used as a detector without special arrangements.

An essential requirement for a detector is that the positive and the negative contacts must not inject holes and electrons into the sensitive area of the detector. Blocking contacts are needed to prevent free exchange
of electrons and holes between the electrodes and the sensitive volume of the detector. A p–n junction beneath the surface of the detector provides this blocking. A thin layer of heavily doped n-type germanium formed at a surface of p-type crystal prevents holes moving into the detector bulk material, even when a voltage is applied across the junction. Positive voltage must be connected to the n-side of the junction, otherwise the system would be a good conductor (major charge carriers attracted by voltage of right polarity). This arrangement of connecting positive voltage to the negative type semiconductor, known as reverse-biased junction, reduces leakage current drastically but allows collecting the free charges produced in the detector material by the energy absorbed from the incident photon. In detector manufacture, blocking contacts are formed on both electrodes; n+ material is used for the positive contact and p+ material for the negative contact.

A diode is a simple and familiar application of the p–n junction. The junction conducts current when the voltage is connected in the forward direction, but it conducts very little when biased in the reverse direction. This reverse bias voltage drives the electrons away from the junction to the n-side and the holes to the p-side (Figure 3).

Thus a large depletion region may be formed. When the donor concentration on the n-side of the junction is much higher than the acceptor concentration on the p-side, the diffusing electrons travel a large distance into the p-type material before recombination with holes; the diffusion of the holes into the n-side is far less efficient. Because the net charge must be zero, as illustrated in Equation (9):

$$N_A d_A = N_D d_D$$  \hspace{1cm} (9)

where \(d_A\) is the depletion thickness inside the acceptor layer and \(d_D\) the depletion thickness inside the donor layer. The depleted volume is the sensitive region of the detector. In that region the concentration of free charge carriers is suppressed by several orders of magnitude. The only remaining charges, the ionized donor sites and the filled acceptor sites, are immobile and do not contribute to the conductivity. The depletion region has a very high resistivity compared with the materials on either side of the p–n junction. Thermal excitation produces some electrons and holes but the electric field sweeps them away immediately.

In a detector, the ionizing radiation produces electrons and holes in the depletion region. At the same time, the leakage current of the reverse biased junction is small, allowing the collection and measurement of the small transient current in an external circuit. The total free charge, i.e. the integral of the current, is proportional to the amount of electron–hole pairs formed, and, consequently, to the energy absorbed in the detector.

A detector is only partially depleted when the depletion region does not extend to the edges of the crystal. Most detectors, however, operate with very high bias voltage and, therefore, the depletion region extends through the full thickness of the semiconductor material (excluding the thin n+ or p+ layers). Such a detector is fully depleted.

The electric potential difference \(\phi\) caused by the charge distribution \(q\) in the region of the reverse biased junction can be calculated from the Poisson equation (Equation 10)

$$\nabla^2\phi = \frac{-q}{\varepsilon}$$  \hspace{1cm} (10)

where \(\varepsilon\) is the dielectric constant of the medium, i.e. \(K\varepsilon_0\) (\(K = 16\) for Ge and the permittivity of vacuum \(\varepsilon_0 = 8.85 \times 10^{-12} \text{ C V}^{-1} \text{ m}^{-1}\)).

Equation (10) is easy to solve in one-dimensional slab geometry.\(^{(1)}\) Assuming a constant charge distribution of \(eN_D\) and \(-eN_A\) on the n+ and p-side of the junction, respectively, the total thickness \(d\) of the depletion layer at voltage \(V\) is illustrated in Equation (11) as:

$$d \approx \frac{2\varepsilon V}{eN_A}$$  \hspace{1cm} (11)

![Figure 3](image-url)
If the p-side doping would be dominant, \(N_D\) should be substituted for \(N_A\). Utilizing Equation (8), allows expressing \(d\) as a function of resistivity, see Equation (12):

\[
d = \sqrt{\frac{2\mu_b \rho_p}{\varepsilon e R}}
\]  

(12)

For a large depletion region, it is necessary that the semiconductor material has high resistivity. This can be achieved, as shown by Equation (11), only if the impurity concentration of the material is very low. In this respect germanium is the best material available; in a modern detector there are, on average, fewer than one impurity atom for \(10^{12}\) Ge atoms.

The depletion region resembles a capacitor (charges separated by an insulator). The larger the depletion thickness, the smaller the capacitance \(C\). Equation (13) shows capacitance \(C\) for a unit area

\[
C = \frac{\varepsilon e}{d} = \sqrt{\frac{\varepsilon e N_A}{2V}}
\]  

(13)

The capacitance of the detector should be as small as possible because this improves energy resolution (section 3.4). Equation (13) shows that the capacitance is minimized by increasing bias voltage until the detector is fully depleted. At larger voltages the capacitance remains constant; the operation of the detector is stable and, furthermore, the charge collection efficiency is improved at the edges of the detector. In a large crystal, \(V\) is typically 2–5 kV. The capacitance is smaller in coaxial geometry than in planar geometry for detectors of equal diameter and thickness (see sections 2.6 and 4.1).

### 2.5 Charge Collection

The rise time of the pulse signal from the semiconductor detector varies considerably depending on the location where the charge carriers are generated within the crystal. In a large detector the electrons or the holes have to travel a few centimeters. Therefore, the charge collection time at saturation velocity of \(10^5\) m s\(^{-1}\) is about 100–500 ns, and, consequently, the pulse rise time is of the same order of magnitude. It is necessary that the shaping time of these pulses in the amplifier is much larger than the longest rise time expected for the detector. Otherwise the energy resolution could be substantially deteriorated as a result of reduced signal amplitudes ("ballistic deficit").

Figure 4 shows the shape of the signal in a depleted planar detector where the electric field is large enough for the charge carriers to reach their saturation velocity. As a result of formation of electron–hole pairs, a constant electric current flows in the external circuit until all free charges have been collected. In practice the detector response is not linear because the free charges are not generated at a point but rather along the track of the ionizing photons and secondary electrons. Furthermore, the electric field may be low at the corners of a cylindrical detector and thus the drifting velocity is low. Such slow pulses may deteriorate energy resolution, causing lower energy tails on the peaks in a γ-spectrum. In addition, charge trapping can reduce pulse amplitude and possible detrapping may affect the leading edge of the pulse. Therefore, the shape and rise time of the pulse vary greatly. In most applications, however, exact timing is usually not required.

### 2.6 High-purity Germanium Detector

Equation (11) allows estimation of the maximum impurity concentration in a semiconductor detector of given size. In a small detector with a depletion thickness of 1 cm and reverse bias voltage of 1000 V, the required net impurity atom concentration should be below $2 \times 10^{16}$ m$^{-3}$. Nowadays an order of magnitude improvement is possible, and thus large and efficient detectors can be manufactured. Detectors with a diameter of 10 cm and a height of 5 cm, or even larger volumes, are now commercially available (see Table 2). Extreme purification has been successful only for germanium.

The manufacture of HPGe detectors, including purification of germanium and production of blocking contacts, is a complicated process and technical details are not always available in the open scientific literature. In principle, bulk germanium, produced in large quantities for electrical industry, is further purified by heating and subsequent removal of the molten zone where the impurities tend to concentrate. The process has to be repeated several times. Lithium evaporation and diffusion are used to produce an n+ layer at the outer surface of a “standard” coaxial p-type crystal, or, alternatively, donor atoms can be implanted using an accelerator. The p+ contact at the inner side of the coaxial p-type crystal is produced by ion implantation of boron or other acceptor atoms. Injection of electrons can also be prevented by a metal–semiconductor surface barrier.$^{(1)}$ The n+ contact may have a thickness or dead layer of 500–700 µm, which significantly attenuates photons with energies below 100 keV (Table 3). However, the thickness of the p+ ion-implanted contact might be only 0.3 µm. If this surface is on the outer part of the crystal, the attenuation of the photons is negligible down to a few keV.

### Table 3 Transmission (%) of photons through the n+ dead layer in germanium (p-type detector) and through Al windows (data calculated with XGAM).$^{(3)}$ If low-energy photons need to be measured, the outer dead layer of the detector has to be small (0.3 µm). Aluminum enclosure with thickness of 1 mm suits photons above 30 keV, whereas a thin beryllium window or a polymer film has to be used for photons below 20 keV.

Recent detector development has made extremely thin n+ coating possible as well.

#### 2.6.1 Planar Detectors

A germanium detector in planar geometry is typically intended for the detection of low energy photons. In a p-type detector the depletion region begins at the n+ contact. At the voltage, predicted by Equation (11), the detector comes fully depleted. At higher voltages the electric field inside the detector increases in a uniform way everywhere in the detector. At the electric field of $10^5$ V m$^{-1}$ (77 K) the electrons reach their saturation velocity of $10^5$ m s$^{-1}$. For holes, a larger field would be required, but this is usually not possible because of breakdown and surface leakage.

In a modern planar detector the rear contact does not cover the full area of the wafer. This design reduces detector capacitance compared with a conventional planar system. Reduced capacitance offers lower noise in the
preamplifier and, consequently, improved energy resolution. Such a detector with a thin beryllium window is very efficient in the energy range of 3–100 keV. Large-area planar detectors with sufficient thickness (30 mm) have very high counting efficiency for environmental samples in a wide energy range (see section 4.1). They are more efficient for nuclides that emit photons with energy below 500 keV than coaxial detectors of much larger volumes.

2.6.2 Coaxial Detectors

Commercial large-volume detectors are traditionally constructed in cylindrical or coaxial format. The outer surface of the cylinder is one electrode, and the second contact is the inner cylindrical surface manufactured by removing the core of the crystal (Figure 5). Usually, only a part of the core is removed so that the outer electrode extends over the other flat end of the crystal. In these close-ended configurations the electric field lines are not radial, as they would be in true coaxial configuration. Thus the charge collection efficiency is somewhat reduced compared with the ideal geometry. There are regions where the electric field is weak and thus the charge collection is not efficient. However, the close-ended configuration provides advantages that compensate for these problems. The planar surface is not vulnerable to leakage currents and provides a good entrance window for weakly penetrating radiation. Distortion of the electric field can be minimized by extending the central hole to near the front surface. In addition, the corners, i.e. those areas where the electric field is weak, can be removed during detector manufacture (“bulletization”).

A well detector provides near $4\pi$ counting geometry for small sources. The energy resolution is, however, usually less than that of the coaxial detectors (Table 4). On request at the purchase phase, the resolution can be improved using special material balancing in the manufacture.

The detector crystal must be kept clean. Traces of impurity at the crystal surface may create leakage currents. The detector is mounted in a housing that maintains a vacuum and provides thermal insulation and protection against surface impurities. Often the preamplifier is also located inside this housing.

To calculate the electric field and potential of the detector, the Poisson Equation (10) has to be solved in cylindrical geometry. The voltage needed to fully deplete the detector is directly proportional to the acceptor concentration in a p-type crystal. The capacitance of the detector with height $h$ (m) is illustrated in

![Figure 5 Coaxial p-type germanium detector. The charge carriers, formed in the pure depleted p-type material, are collected by the electrodes. However, the dead layer, i.e. the thick n+ layer, effectively absorbs low energy photons. In an n-type detector, the thin p+ layer is facing outwards. With a thin beryllium window the response of an n-type detector extends below 5 keV. In this detector the holes are collected by the outside electrode and they have, on average, a shorter distance to travel. This reduces efficiency of hole trapping and consequently, an n-type detector is not as vulnerable to radiation damage as a p-type detector of equal size.](image)

\(^{a}\) n+ impurity region at the entrance, Al enclosure not included.
\(^{b}\) Entrance contact produced by ion implantation.
\(^{c}\) 3 keV for an extended range detector with very thin outer n+ layer and Be window.
\(^{d}\) A thick planar detector (30 mm) has excellent energy response below 500 keV and its useful energy range extends up to 2 MeV.
Equations (14) and (15)

\[
C = \frac{2\pi \hbar}{\ln(r_2/r_1)} \tag{14}
\]

or

\[
C(\text{pF}) = \frac{890\hbar}{\ln(r_2/r_1)} \tag{15}
\]

For good energy resolution, the detector capacitance should be as small as possible. Therefore, the ratio of core-to-crystal radii, \( r_2/r_1 \), should be minimized. For example, the capacitance of the detector with dimensions in Table 2 is expected to be 20 pF.

The shape and the dimensions of the detector have to be chosen according to the needs of the application (section 4.1). A large-volume detector is not the best solution for all applications.

### 3 ENERGY RESOLUTION OF THE SPECTROMETER

The energy resolution qualities of germanium detectors provide an efficient means of detecting and resolving a peak of a nuclide from baseline continuum or from a neighboring peak in the \( \gamma \)-spectrum (see Figure 17). The photo-peak pulses are concentrated into a few channels, and thus a peak may be found above the background noise that would otherwise mask the primary signal, as often happens in low-resolution spectrometry.

Uncertainty of charge production, incomplete charge collection and noise of the electronic equipment determine the total energy resolution of a measuring system based on a semiconductor detector. These uncertainties are independent of each other and are therefore additive. Thus, the width \( w \) of a peak can be divided into components as\(^{1,5} \) illustrated in Equation (16)

\[
w^2 = w_p^2 + w_c^2 + w_n^2 \tag{16}
\]

where \( w_p, w_c \) and \( w_n \) refer to the uncertainty in production of charge carriers, in charge collection, and in electronic noise respectively.

#### 3.1 Full Width at Half-maximum

In high-resolution \( \gamma \)-spectrometry, the resolution of the measuring systems is described by the full width at half-maximum (fwhm) of the photo-peak (Figure 6). In low-resolution spectrometry, however, it is common practice to express the resolution in percentages (fwhm normalized by the photo-peak energy). For example, a good NaI detector may have an energy resolution of 6% at 662 keV that corresponds to fwhm of 40 keV.

An ideal photo-peak can be described by the Gaussian distribution, illustrated in Equation (17), as

\[
C = \frac{A}{\sqrt{2\pi} \sigma} e^{-\frac{(E-E_0)^2}{2\sigma^2}} \tag{17}
\]

where \( C \) is the number of counts per energy interval, \( E \) the energy, \( E_0 \) the energy of the peak centroid, \( \sigma \) the standard deviation of the distribution, and \( A \) the peak area. The baseline under the peak has to be subtracted in a proper manner. Often a constant or linear approximation across the baseline of the peak is sufficient. Spectrum analysis programs fit a Gaussian curve or a modified Gaussian

![Figure 6](image-url) Verification of resolution and peak shape. The measurement was performed with a \( ^{60} \)Co source of 5.6 kBq (the detector is described in Table 2). Both curves represent same data. One channel corresponds to 0.33 keV. fwhm can be estimated in different ways. The most straightforward solution is based on peak area (11740) and peak height (1863). Equation (20) gives an estimate of 5.34 channels or 1.79 keV for the fwhm. The logarithmic display of the pulse height distribution reveals that the shape of the peak is not completely symmetric. At the rising part of the peak there is a clear tail that is caused by incomplete charge collection or electronic noise. Fine tuning of the measuring system should be adopted to further improve the quality of the spectrometer.
curve to the measured distribution describing the peak shape (section 6.4).

Equation (17) gives the relationship between the fwhm and \( \sigma \) and the result is Equation (18):

\[
\text{fwhm} = 2\sqrt{2\ln 2} \sigma = 2.355\sigma
\]  

(18)

Therefore, Equation (16) can be written as shown in Equation (19):

\[
\text{fwhm}^2 = \text{fwhm}_p^2 + \text{fwhm}_c^2 + \text{fwhm}_n^2
\]  

(19)

The fwhm can be estimated from the calibration data by simple interpolation. For high accuracy, the peak areas should be large (>10^4 counts). This general method does not depend on any assumptions of the peak shape.

If it is appropriate to assume a Gaussian shape, a convenient way to calculate the fwhm is based on the peak area \( A \) (channel-by-channel summing and appropriate baseline subtraction) and peak height \( C(E_0) \), shown in Equation (20), as in Equations (17) and (18):

\[
\text{fwhm} = \frac{2.355}{\sqrt{2\pi}} \frac{A}{C(E_0)} = 0.939 \frac{A}{C(E_0)}
\]  

(20)

Full width at one-tenth maximum (fwtm) and full width at one-fiftieth maximum (fwfm) describe the peak shape near the baseline more appropriately than the fwhm does. fwtm and fwfm should not be calculated by the area method, however. Their ratio with fwhm is compared with \( \frac{\text{fwtm}}{\text{fwhm}} \) and \( \frac{\text{fwfm}}{\text{fwhm}} \) should be below 1.9 and 2.5 respectively.\(^{(11)}\)

### 3.2 Uncertainty of Charge Collection

The uncertainty of charge production in a semiconductor detector was discussed in section 2.2. Table 5 shows the fwhmp values for the Fano factors between 0.06–0.10 (see Table 4). These uncertainties are idealistic lower limits of the detector resolution.

The average energy \( W \) to create an electron–hole pair depends on temperature (\( \Delta W/W = 2.53 \times 10^{-4} \) per K).\(^{(12)}\) Temperature variations during the measurement shift the position of the peak and, thus, the final peak at the end of the acquisition period is broadened. Temperature increase of one degree moves the position of a peak near 1 MeV by 0.25 keV. Therefore, high-resolution measurement is only possible after temperature equilibrium is reached. A sufficiently long time (1 day) should be allowed for cooling the detector, and the temperature of the surroundings should be kept unaltered during the counting of the sample. A digital spectrum stabilizer is one option for compensation of temperature drifting (section 5.4).

The temperature of the crystal can be recorded using the connection in the detector that gives the HV shutdown signal. The internal temperature resistor changes from 100 \( \Omega \) at 77 K to 540 \( \Omega \) at room temperature. With 1 mA current the voltage changes from 100 mV to 540 mV, i.e. 2 mV K\(^{-1}\). So an external 10-bit analog-to-digital converter (ADC) with the proper input range (say 1 V) would give a resolution of 1 mV or 0.5 K. The temperature measurement is implemented in commercial detectors, but only for the protection of the detector against warming and subsequent damage of the preamplifier (detectors built before 1998). However, the continuous demand toward higher quality creates pressure to include various state-of-health indicators in the measurement system, including recording of the temperature of the crystal.

### 3.3 Uncertainty of Charge Collection

Incomplete charge collection may be a problem in large detectors where the charge carriers have to travel long distances. The peaks in the spectrum may have a low-energy tail that makes spectrum analysis more difficult and masks small peaks near a larger photo-peak. Impurities or crystal defects trap charge carriers. In a strong electric field some trapped charges may be released within the rise time of the preamplifier signal, whereas other charges do not contribute to the pulse at all.

The manufacturers design the detectors to avoid regions with low electric field, and the detectors are operated with a bias voltage as high as possible. In modern detectors the efficiency of charge collection is very near 100%. However, spectrum analysis software should be able to cope with peaks that have tails.

### 3.4 Electronic Noise

Electronic noise in the preamplifier and in the other signal processing equipment causes uncertainties in pulse height and shape that has significant effects on the overall resolution of the spectrometer. The preamplifier produces most of the noise. Any uncertainty in the front end of the signal processing is magnified by the main amplifier. The contribution of the noise to the resolution can be measured by injecting a suitable charge \( (\text{C}E_0/W) \) to the input of the preamplifier. This charge may be generated by a radiation source and a detector,
or by a pulse generator through a capacitor (known as charge terminator). For estimating the system gain, \( V_0/E \), the output pulse height \( V_0 \) at the main amplifier has to be measured. The preamplifier noise is equivalent to the root-mean-square voltage \( V_{\text{rms}} \) at the output of the main amplifier in the absence of any pulses,\(^5\) see Equation (21)

\[
f_{\text{whm}} = 2.355 \frac{E}{V_0} V_{\text{rms}} \quad (21)
\]

The capacitance of the detector and the capacitance of the cabling between the detector and the preamplifier should be as small as possible. Typically, the external capacitance is between 10–40 pF (section 2.5). Other sources of noise are the input field effect transistor (FET), the resistance connected to the input, and the leakage currents from the detector and the FET.

The electronic noise is a constant, independent of energy. Therefore, it dominates total fwhm at low energies. Above 1 MeV the uncertainty of charge production and collection is more important than the noise from electronic equipment.

The electronic noise has two major components. Parallel noise (step noise) results from detector leakage current and from thermal noise in the feedback resistor of the preamplifier. A low count rate, large feedback resistor (1000 M\( \Omega \)), cooling, and a short time constant in the amplifier (section 5.2) minimize the parallel noise. Some preamplifiers do not need a feedback resistor at all (section 5.1). Series noise (delta noise) depends on the total capacitance at the preamplifier input. To reduce series noise, the main amplifier should be operated with long time constant. This requirement is in conflict with the parallel noise optimization. In practice a time constant of 3–6 µs minimizes the total noise. The FET and the feedback resistor are the critical parts of the preamplifier and for reducing noise, they are normally mounted together with the detector for the operation at low temperature.

The noise of the electronics is dominating the total resolution at energies below 300–500 keV. A state-of-the-art general-purpose detector has fwhm of 750 eV at 122 keV (data sheet by the manufacturer); in practice the resolution could be as good as 600 eV. Such performance opens completely new possibilities for \( \gamma \)-spectrometric nuclide determination. For example, the peaks of \(^{235}\text{U} \) (185.7) and \(^{226}\text{Ra} \) (186.1 keV) may be resolved using high-quality deconvolution algorithms. The task is inaccurate or impossible for detectors with a noise level above 1000 eV (see Figure 17).

### 4 GERMANIUM DETECTOR AND ITS OPERATION

#### 4.1 Counting Geometry and Detector Selection

Sufficiently high resolution and counting efficiency are the key requirements for germanium detectors, and their specifications should be chosen according to the particular application. A thick large-volume detector is a good solution for high-energy photons (>1 MeV), but it is not necessarily the optimum choice for normal environmental analysis where the emphasis is more on low and medium energies (<1 MeV). Increasing the volume of the detector improves counting efficiency but, unfortunately, also increases the background count rate, with a consequent reduction in the detection capability. The cost is reduced by choosing a detector with optimum dimensions.

Detector manufacturers specify products according to the concept of relative efficiency, where the efficiency of HPGe detector is quoted relative to that of an 3” × 3” NaI detector for the 1.33 MeV photons of \(^{60}\)Co, with a 25-cm source detector distance. The relative efficiency is the ratio, expressed as a percentage, of the corresponding detection probabilities of the two detectors with full-energy peaks. A “100% detector” has a counting efficiency of \( 1.2 \times 10^{-3} \) for 1.33 MeV photons of \(^{60}\)Co at a source detector distance of 25 cm.\(^{13}\) Although relative efficiency is the basic quantity for specifying the performance of the detector, this parameter is far too simple to be used as the key specification in the purchase of a detector. The overall counting geometry, including the shape of the sample and the dimensions of the detector, must be optimized.

The environmental samples may contain high-energy background nuclides, such as \(^{40}\)K (1460.8 keV) or \(^{208}\)Tl (2614.5 keV), which make the detection of low-energy peaks more difficult. The Compton continuum in a \( \gamma \)-spectrum results from Compton interactions in the detector and its surroundings (section 2.1). The peak-to-Compton ratio is defined as the ratio of the height of 1.33 MeV \(^{60}\)Co peak to the average Compton plateau between energies 1.040 MeV and 1.096 MeV. An ideal detector to determine low amounts of unknown radionuclides has a high counting efficiency, good energy resolution (fwhm < 2 keV at 1.33 MeV and <0.8 keV at 122 keV), large peak-to-Compton ratio (>70), and optimized dimensions for the sample and energy of interest.

The coaxial p-type detector has been the standard choice for environmental \( \gamma \)-spectrometry (section 2.6), whereas n-type detectors provide detection over a larger energy range but are more expensive. The greater efficiency of the n-type detector at low energies also increases the summing of X-rays. If nuclides with photon energies below 60 keV, such as \(^{241}\)Am (59.5 keV) or \(^{210}\)Pb
Where \( K \) and \( R \) and expressions are illustrated by Equations (22) and (23)

\[
R_{\text{eff}} = \frac{V}{4.3} \quad \text{(22)}
\]

and \( R_{\text{eff}} = KD^\alpha L^\beta \quad \text{(23)}
\]

where \( K = 243.21, \alpha = 2.8155, \beta = 0.7785 \) and \( D \) is diameter (decimeters) and \( L \) length (decimeters). A 100% detector has a volume of about 400 cm\(^3\). The price of the detector is proportional to the volume and, consequently, to the relative efficiency. A cost–benefit analysis is certainly warranted to optimize the performance of the counting system.

The first step in detector selection is to define the energy range of interest and decide at which energy, i.e. for which nuclide the detection capability should be optimized. The sample geometry plays a major role in the selection of the dimensions of the crystal.

Let us consider the selection of an HPGe crystal for an air surveillance program that is intended to detect trace amounts of fission products. The energy range of interest is 60–1800 keV. Furthermore, the system specifications require that the minimum acceptable relative efficiency is 40%, and \(^{140}\)Ba is the key nuclide for which the detection limit is defined (section 6.5). In high-volume air sampling the area of the filter is about 0.1 m\(^2\). For efficient counting, this area has to be reduced to the size that is of the same order of magnitude as the detector dimensions. In the laboratory the sample can be pressed into tablet form, with a diameter of 45 mm and thickness of about 6 mm (this is referred later as a “small” sample). Another sampling device might produce samples that have a diameter of 80 mm and thickness of 10 mm (“large” sample). The task is to find the optimum detector for both types of samples. The counting efficiency should be high, but the detector volume should be as small as possible (to reduce costs and baseline in the spectrum).

The primary photons of \(^{140}\)Ba have an energy of 537 keV; more than 90% of these photons (axial direction) interact in a germanium crystal with a thickness of 55 mm (Figure 7). Increasing the thickness (volume) of the detector would not greatly affect the photo-peak count rate (although the first interactions are mainly Compton scattering). However, a larger thickness would increase the level of baseline in the spectrum because the air sample and the surrounding construction materials contain natural radionuclides (\(^{208}\)Tl and \(^{40}\)K) which emit high-energy photons. The required detection limit can therefore be attained without incurring the cost of a large-volume detector.

Relative efficiency as a function of detector dimensions is shown in Figure 8. This diagram, together with Figure 7, can be used for the selection of the detector. The optimization of the detector is based on the dimensions...
of the sample and the energy interval of interest. A 40% detector (A) with thickness of 55 mm and diameter of 62 mm would fulfill the minimum requirements for the small samples. However, the counting geometry would be inefficient for the large samples, and therefore the detection limit would be high. Detector B with diameter of 80 mm would be a good choice for both cases. It may cost twice as much as the detector A, however. Detectors C and D are thinner (45 and 40 mm), but they may still give lower detection limits for $^{140}$Ba than the thicker detectors; in a critical application this should be verified experimentally or theoretically, perhaps by Monte Carlo simulations. Detector D may cost 10 000–15 000 US$ less than the detector B. Detectors E and F could be built in planar geometry (Figure 9). Equipment suppliers should be requested to offer these different types of detectors.

A tendering process based on relative efficiency alone is not sufficient to guarantee good detection performance. Detectors already present in a laboratory should also be optimized for their particular application. Sample counting geometry might have to be modified to suit the dimensions of the detector.

Until recently detector manufactures seem to have had little interest in producing standard detectors with similar characteristics, and customers have been happy to receive better than expected performance (in terms of relative efficiency). Every detector is thus an individual, and has to be meticulously calibrated by the user.

Modern detectors can be cloned with high accuracy. These detectors first became available commercially in 1998. Such detectors can be calibrated by the manufacturer or by special laboratories for a few counting geometries. Because the properties of the standard detectors are well known, reliable efficiency curves can be calculated for any type of sample (section 6.2.2.2). Furthermore, this computational calibration approach provides the means to take into account the variability of the sample density.$^{14,15}$ A broken standard detector can be replaced quickly, whereas it may take several weeks to recover from the breakdown of a nonstandard detector because of the calibration requirements (for verifying detector performance see quality assurance procedures in section 8).

Optimization of the detector dimensions gives the best performance with the lowest costs. The adoption of commercial, optimized, standard detectors should give several advantages to the users. The capital costs and the running costs could be greatly reduced and, furthermore, the quality of the measurements could be improved.

### 4.2 Sample Preparation

Sampling strategies and sample preparation techniques are crucial for the success of environmental monitoring programs. To achieve low detection limits, the sample volume has to be reduced to match the detector dimensions. An ideal sample would be a point source of zero mass. In practice, the whole sample, or a small aliquot, has to be placed in a container of optimized dimensions.

A narrow beaker (Figure 10) with a diameter far less than the diameter of the detector suits samples of small volume ($<$30 cm$^3$). To avoid self-absorption at low energies in samples with high density (soil, sediment, etc.), a wide beaker should be considered for volumes larger than 15–20 cm$^3$.($^{14,15}$)

If the diameter of the container and the detector are of roughly equal size, the container can be used for a large range of sample volumes, up to 300–500 cm$^3$, depending on the diameter of the detector. A Marinelli container (Figure 10) provides superior counting efficiency for very large volumes.

Environmental samples have different origins, for example gaseous, aquatic, soil, air filter, food and biota sample, with various shapes and volumes. The...
laboratories must develop procedures to cope with these different samples. Standard counting geometries, for which detector efficiency calibrations have been performed, are necessary.

Surface water may be sampled with open-mouthed bottles, whereas immersion-type devices can be opened at the selected depth below the surface. Pumping devices allow collecting large volumes of water. Water samples are vaporized in a warm closet (105°C). A good practice is to use porcelain evaporating basin covered with double cellophane foil.

Bulk water samples should be filtered to trap the sediment. Filters containing suspended particulates must be dried before measurement. Both water and filtered sediment should be analyzed because sorption in sediment and accumulation in biota may enrich radionuclide concentrations.

Some fungi, lichens, and moss are sensitive indicators of environmental contamination because they concentrate radionuclides by a factor of 10–100 (compared with soil concentration). Biota samples should be weighed (wet samples) and ashed in a furnace to accomplish complete decomposition. An aliquot of blended ash in a small beaker is a good sample counting geometry.

There are two practices for ashing. Dry ashing is performed by charring the sample at 400–450°C and/or ashing it at 600°C. Wet ashing uses acids to chemically destroy organic components in the sample. Dry ashing is suitable only if the element of interest is nonvolatile. Iodine, for example, tends to escape from the sample during the heating. Wet ashing utilizes concentrated nitric, hydrochloric and sulfuric acids, with heating to temperatures above 100°C. Because of high acid concentration and temperature, sample handling must be performed with great care.

A coring tool is needed for soil and peat sampling. The tool could be a smooth steel bore tube, with soils removed by internal pressure, or a modified golf-course hole cutter, fitted with extended blades that can be removed to collect intact and whole samples. For radionuclide depth distribution analyses, the cores can be sectioned at suitable intervals. Each sample must be placed into an air-tight container to retain moisture. At the laboratory the samples are screened to remove objects larger than 2 mm in diameter, weighed and dried, usually for a few days at temperatures of 105°C, and then crushed and homogenized (particle size < 100 μm). Samples are again weighed and placed in standard containers (the volumes are typically between 50 and 150 cm^3). Particular attention has to be paid to the quality assurance of the detector efficiency calibration (see section 6.2).

Air filter samples have a large surface area. The goal of the sample preparation is to produce a tablet with diameter equal to or smaller than the detector diameter (section 4.1). Before pressing, the sample could be wrapped in a thin cellulose paper. Such a procedure results in a sample which has a clean outer surface. Therefore, several samples can easily be piled for one composite sample. Another elegant sample treatment method is to utilize a robot that cuts the filter into small, cloned pieces. Because no pressing device is used, the sample slices are ideal also for autoradiography, which may reveal the particulate nature of the debris and allows isolating single particles for more detailed analysis, including γ-spectrometry.

If extremely low detection limits are required for certain radionuclides, methods of radiochemistry could be applied to get rid of the sample matrix and disturbing inherent natural radioactivity. For example, the following procedure could be used for cesium separation. A small amount of stable cesium carrier (20 mg) is added to the sample, which is then wet ashed with nitric and hydrochloric acids. Cesium is coprecipitated by ammonium molybdophosphate. The resulting homogeneous, thin precipitation has a small mass and contains only cesium, without any interfering nuclides present.

By choosing the appropriate radiochemical procedures, it is possible to achieve significant improvements in detection sensitivity. However, one of the major attractive features of γ-spectrometry is that fundamentally it is a nondestructive technique. Therefore, chemical manipulation of samples should only rarely be resorted to. If extensive chemical treatment is required, then other techniques, such as inductively coupled plasma mass spectrometry, should be considered.

4.3 Cooling Systems

The most common cooling system is based on an isolated dewar filled with liquid nitrogen in thermal contact with the detector. The crystal and the front-end components of the preamplifier are housed in a clean vacuum chamber, which is attached to or inserted into a dewar.

The detector chamber and the preamplifier are packaged together in a compact aluminum cylinder, known as “end cap”. Cooling is provided through a pedestal that connects the copper “cold finger” to the liquid nitrogen reservoir. Part of the detector housing is evacuated to provide thermal insulation. “Sweating” of the detector or the dewar is an indication of vacuum insulation problems.

Electrical cooling is operationally simpler than a liquid nitrogen system. Although the investment costs are higher, the running costs are lower during the detector lifetime. The electrically refrigerated cryostat should therefore be considered as an alternative in all applications, even where a supply of liquid nitrogen is available.
The first electrically cooled detectors utilized closed-cycle freon and helium refrigeration. The quality of the equipment was not sufficient to provide $\gamma$-spectra with resolution that is achievable with liquid nitrogen cooling. In addition, they had moving parts, which made maintenance necessary at short intervals. Advances in the development of electrical cooling systems have solved the operational and resolution problems encountered in the past, and nowadays, the quality of the $\gamma$-spectra is excellent. Commercial equipment uses an air-cooled compressor, which supplies refrigerant to the cold head capsule. The compressed refrigerant expands and cools the detector. Because the cold head has no moving parts, the resolution does not deteriorate because of microphonics, the maintenance costs are low, and the system has a long expected service time (>5 years). The cooling system weighs 20–30 kg and the power consumption is about 500 W. No external pumping is needed. The refrigerant (<100 g) is flammable but is chlorofluorocarbon (CFC)-free.\textsuperscript{5,11}

Electrically refrigerated cryostats are designed to operate at ambient temperatures of 10–35 °C. Unlike liquid nitrogen-cooled detectors, which have a stable temperature as a result of the boiling nitrogen, electrically cooled detectors are prone to temperature drifting, with resulting resolution deterioration, unless the ambient air temperature is carefully controlled. The monitoring of the temperature of the crystal at short intervals, perhaps every 10 minutes, provides an external state-of-health signal that can be measured at low cost (section 3.2).

### 4.4 Detector Shielding

Shielding of the detector is of vital importance in low-level counting because it reduces the amount of background radiation reaching the detector. The environmental background comes mainly from $^{40}$K in natural potassium, from nuclides in the decay chains of uranium and thorium, and from cosmic radiation. The background reduction is an art of its own and may contain various passive and active measures. Often the sample itself is the dominating source of background. A practical goal in environmental applications is to attenuate external background radiation by a factor of 1000.

A laboratory dedicated for low-level counting should be designed using materials of low natural activity. Concrete is often the main construction material, and it should be made of sand with low activity of potassium (<100 Bq kg$^{-1}$), radium (<5 Bq kg$^{-1}$) and thorium (<5 Bq kg$^{-1}$). Neutrons, induced by cosmogenic muons, interact with the germanium crystal and the surrounding materials generating photons that may be detected in low-level counting. Neutron fluence rate is reduced in a laboratory that is located underground or, at some extent, in ground floor of a large building. The background related to radon daughters can be reduced, if needed, by flushing nitrogen or clean air into the surroundings of the detector.

The shielding of the detector is usually constructed of lead. Steel is another possibility, but it has some serious drawbacks. Firstly, to attenuate 1 MeV of photons by a factor of 1000, requires 147 mm of steel but only 87 mm of lead.\textsuperscript{13} Secondly, modern steel is often contaminated with $^{60}$Co; pre-World War II steel might be expensive and difficult to get. Thirdly, Compton scattering is more dominant in steel than in lead, increasing backscatter from the shielding.

The conventional design of detector shielding is based on 100–150 mm of lead. A thicker lead shield does not provide further background reduction because of the enhanced interaction with cosmic rays. Backscatter is minimized by making the detector shield distance as large as possible (>100 mm).

The photoelectric absorption of $\gamma$-radiation by lead inevitably produces fluorescent X-rays. The shielding should therefore have an inner layer that is designed to absorb low-energy photons. A typical “graded-Z” shield consists of cadmium and copper or tin. Cadmium absorbs X-rays of lead (72.8 keV, 74.9 keV, 84.8 keV, and 87.3 keV). The copper layer absorbs the X-rays from cadmium (22 keV) and provides further attenuation of X-rays from the lead.

The thickness of the liner materials varies widely; a commercial design, intended to attenuate Pb X-rays by a factor of 100,\textsuperscript{11} has a liner with 0.5 mm of cadmium and 16 mm of copper, whereas another design is based on tin (1 mm) and copper (1.5 mm).\textsuperscript{9} Cadmium is a toxic material and it has a high neutron cross-section resulting in prompt emission of 558 keV photons; furthermore, the neutron activation product $^{109}$Cd emits 88 keV photons. Because of difficulties in material handling and possible inconveniences in spectrum analysis, it should be carefully assessed whether cadmium really is needed for the shielding. In practice, a simple shield liner based on tin (1–2 mm) and copper (1–2 mm) is often sufficient for $\gamma$-spectrometry of environmental samples, particularly if the low-energy photons are not of major interest.

Shielding material may contain natural $^{210}$Pb, and the shield liner absorbs its 46.5 keV radiation. The $^{208}$Bi, decay product of $^{210}$Pb, is a beta emitter ($E_{\text{max}} = 1161$ keV), however, and its bremsstrahlung generates a continuum up to 500 keV.\textsuperscript{9} A careful design of a lead shield would contain two types of lead. The outer layer could be ordinary lead, whereas the inner layer (10–30 mm) could contain special old lead with low $^{210}$Pb content (<20 Bq kg$^{-1}$).\textsuperscript{9} The aged lead should be much older than the half-life of $^{210}$Pb (22 years). However, if the
sample itself, such as an air filter, contains large amounts of natural beta and γ-emitters, the special lead liner does not improve detection limits of fission products or other nuclides of interest.

Active background shielding is based on anticoincidence counting designed either for the reduction of Compton continuum or for the removal of the contribution of high-energy cosmic radiation. The latter system, known as veto detector, is relevant for the counting of environmental samples only if the overall background is dominated by the counting environment. The veto detector is installed above the lead shielding, and it may improve nuclide detection limits by a factor of two. However, the guard detector itself must be shielded against environmental radiation (false coincidences with the HPGe detector). The system is complex and expensive, and, consequently, it is used only in special applications.

Compton suppression systems utilize a large “guard” detector (NaI detector for example) that surrounds the germanium detector. If a primary photon leaves only part of its energy in the germanium detector and the escaping photon interacts with the guard detector, the processing of the HPGe signal is stopped by the guard system that sends a triggering pulse for closing the input gate of the recording electronics.

Active shielding may reduce the Compton continuum by a factor of ten and, consequently, the peak-to-Compton ratio may increase to 1000:1. A background suppression of 10 translates to the reduction of the detection limit by a factor of three (section 6.5). This improvement would be crucial for low-level determinations of some nuclides, 137Cs in particular. However, the anti-Compton systems are technically complex and can handle only small samples. The most serious drawback is the suppression of full-energy peaks of nuclides that emit photons in cascade (60Co, etc.). Peaks are suppressed also by random coincidences in the HPGe detector and in the guard detector. Because of these drawbacks, the counting system should not only register the suppressed spectrum but also the original nongated spectrum.

5 MEASUREMENT ELECTRONICS

The signal processing of an HPGe detector is based either on traditional analog electronics or on modern compact digital devices. These two technologies handle the signals coming from the detector in different ways.

In the analog device, the charges created and collected in the detector are transformed, shaped and amplified to a large voltage pulse. This pulse is thereafter converted to a digital form by a fast and stable ADC.

In the digital device, the pulse generated by the preamplifier is digitized and there is no need for an amplifier or ADC. The most advanced digital equipment can handle overlapping signals normally rejected by the analog amplifier due to false signal shape. Digital signal processing also provides excellent temperature stability for peak position and shape.

5.1 Preamplifier

The main functions of the preamplifier are to convert the charge generated at the detector to a voltage pulse, to amplify the signal and to transfer the pulse to the main amplifier.

The charge created in the detector is so weak (5.4 \times 10^{-12} \text{C MeV}^{-1}) that it cannot be used directly for the radiation detection. Preamplifiers designed for \(\gamma\)-spectrometry are charge-sensitive and produce output pulses with amplitude proportional to the integrated charge, i.e. to the energy received from the incident photon. An advantage of the charge-sensitive preamplifier is that a change in the input capacitance has no effect on the output voltage (Figures 4 and 11). The total capacitance of the detector has, of course, a crucial importance for resolution (section 3.4).

The preamplifier is located close to the detector to avoid noise caused by the capacitance in the wires between the preamplifier and the detector. The pulse from the preamplifier has a short rise time but a long decay time (around 50–100 µs). Therefore, pulses with different charge collection times can be handled. A preamplifier does not usually have pulse-shaping capability.

The rising edge of the preamplifier pulse carries the information on radiation energy. The main amplifier extracts this information for further processing. However, at high count rates, the piling of pulses in a typical preamplifier with RC-feedback may be a problem. The average DC voltage level may become too large to preserve linearity between charge and pulse height. At very high count rates, the DC voltage may rise to near the supply voltage of the preamplifier (24 V). Then, saturation or paralysis has to be taken into account, particularly in applications intended for emergency preparedness. Count rate performance is described in terms of energy rate; a typical preamplifier has a safe working level below 10^5 \text{MeV s}^{-1}.

The noise of the preamplifier is reduced in a design with no feedback resistor, and where the charges accumulate in the capacitor \(C_F\) (Figure 11). This results in a stepwise rise in the output voltage; each step is the result of a separate charge collection process. From time to time the output has to be reset to the zero level to prevent the system exceeding the saturation level. This kind of resetting is performed using optical feedback or transistor reset.
Optical feedback provides the lowest noise, but transistor feedback is useful in high-count rate systems.

5.2 Amplifier

The purpose of the amplifier is to convert the output signal from the preamplifier into a form that is suitable for the application, for the ADC in particular. Signal amplification is only one of the roles of the amplifier. Pulse shaping is the primary function of the instrument. Another important feature is the rejection of piled pulses at high count rate. Furthermore, pole-zero cancellation (Figure 12) and baseline restoration (see later) are needed to compensate for undesirable consequences of the signal processing. The modern amplifier is a very sophisticated instrument which would more appropriately be named as signal processor or pulse processor.

Since the preamplifier signal decays slowly toward the baseline, each new pulse is added on the tail of the previous pulse. The amplifier restores the baseline reference level between pulses by differentiation (Figure 12). To reduce noise and to measure the amplitude accurately, the signal has to be integrated. The differentiator is a high-pass filter and the integrator is a low pass filter. The initial long preamplifier signal is converted to a short pulse that can be handled by the ADC. The shaping time constant (Figure 12) has to be optimized for each counting system. For small HPGe detectors the optimum time constant is 2–4 µs, whereas the large detectors need a longer period of 4–10 µs. Reducing shaping time increases detector throughput at the expense of resolution. The shape of the output pulse is often semi-Gaussian, and the height of the pulse is proportional to the original energy absorbed by the detector. The semi-Gaussian shape is achieved by a single differentiator followed by two active integrators. The active circuits are superior to passive RC integrators, particularly for pulse symmetry and for signal-to-noise ratio.

Pile-up, also known as random coincidence summing, is a process where two or more photons arrive to the detector simultaneously or almost simultaneously. At high count rate the preamplifier pulses may be piled. If such a signal goes through the amplifier, the ADC may then misinterpret the ill-conditioned pulse. Therefore the piled pulses have to be rejected using a special pile-up-rejector (PUR) which ignores pulses that are too close to each other. PUR improves the quality (peak-to-baseline ratio) of the spectrum by reducing the summation effect of two independent photons.

The unipolar output pulse of the amplifier has to be normalized to a DC reference that is usually 0 V. Baseline stabilization ensures that the successive pulses are precisely quantified. The simplest baseline restorer is just a CR differentiator. The correction circuit guarantees that the average signal area above ground equals the average signal area below ground. To prevent the introduction of noise, the time constant of the differentiator must be at least 50 times larger than the shaping time constant of the amplifier. At low count rate the baseline between the pulses remains near the ground potential. However, at high count rate the baseline must shift down. This can be
corrected by a gated baseline restorer that connects the CR circuit to ground only between the pulses.

### 5.3 Analog-to-digital Converter

ADC is intended for the conversion of the amplifier pulses to a digital form. The ADC converts the height of each analog pulse to a number, i.e. to a sequence of bits representing the energy of the incident photon. The output of the ADC specifies the channel in the MCA at which one count will be stored for each output pulse of the same size. The final result of the process is a pulse height distribution, i.e. an energy spectrum.

In the “Wilkinson ADC”, the pulse charges a capacitor. Thereafter the capacitor is discharged at a uniform rate. The time of the discharge is proportional to the initial maximum charge on the capacitor. The discharge time is measured with high precision using a clock (100–500 MHz) that receives a gate signal at the beginning and at the end of the discharge. The Wilkinson ADC has excellent linearity but the digitization time varies according to the pulse height.

In the “successive approximation ADC”, a fixed time is used for the analog-to-digital (AD) conversion. The initial analogue pulse is stretched and then compared several times with a changing reference voltage. During the process the channel that represents the pulse is generated bit by bit. For example, a conversion process with 12 stages has a resolution of 12 bits, i.e. 4096 channels. The conversion time in the successive approximation ADC is typically 10µs, but the fastest instruments need less than 1µs.\(^{(9,11)}\)

Conversion gain of the ADC refers to the number of channels in the spectrum. In high-resolution \(\gamma\)-spectrometry this setting is between 4096 and 16384 channels (14 bits). The dynamic range at which the ADC is working can be reduced using lower and higher level discriminators which select the voltage range for the ADC. These settings are practical if there are lots of pulses beyond the energy range of interest. All the pulses converted in vain increase dead time of the measurement system.

Dead time is the time required for pulse shaping and AD conversion. During this period the system is not able to handle new incoming pulses. The dead time depends on the pulse rate and equipment conversion times. The dead time and its complement, the live time, are calculated during the spectrum acquisition by the computer that controls the measurement. The live time is the actual time during which the system collects counts. For proper timing, a live time clock is a common solution that works well at low count rates because all MCA dead time losses are manifested at its input gate. A further development is the Gedcke–Hale method that compensates also for the losses due to the leading edge pile-up in the amplifier.\(^{(5,11)}\)

To verify the dead time reported by the measuring equipment, the actual throughput of the system can be checked in a simultaneous measurement using a sample and a standard source. The procedure is as follows:

1. Verify that the sample does not produce a peak at the same location as the standard source.
2. Measure the pulse rate of the standard source for the peak of interest. The pulse rate is calculated as the ratio of the counts detected at the peak divided by the live measuring time reported by the hardware.
3. Repeat the measurement for the sample and the standard source simultaneously.
4. Compare pulse rates above. The system hardware reports correct live time (and dead time) if the pulse rates are equal.

Another possibility to verify or to calculate the dead time is the following procedure:

1. As above.
2. Measure the count rate from the calibration source. Verify that the dead time is zero (a weak source). Calculate the peak count rate as the ratio of the peak area to the real measuring time.
3. Repeat the measurement for the sample and the standard source simultaneously. Calculate the peak count rate as the ratio of the peak area to the real measuring time.
4. Calculate the live time and the dead time (in percentages) by dividing the pulse rates in points 3 and 2.

The standard source above can be replaced by a high-quality pulse generator.

### 5.4 Spectrum Stabilization

A digital stabilizer may be needed for an MCA in unstable conditions, such as when temperatures may vary. The most common way to stabilize the spectrum is to use a radioactive source that has one peak at low energy and another peak at high energy. The amplifier zero and gain and the ADC are then adjusted in real time to compensate for any drifting. Another possibility is to use a pulse generator. For low-level counting this method is preferred because it produces no Compton continuum (section 2.1). On the other hand, from the operational point of view a pulse generator is much more complicated and unreliable than a simple point source.

### 5.5 Digital Signal Processing

Traditional \(\gamma\)-spectrum acquisition hardware includes several devices. Firstly, the preamplifier converts the
charged created in the detector to a voltage pulse. Secondly, an amplifier shapes the pulse to a form suitable for the ADC and, finally, the ADC determines the height of the pulse in digital units. Each one of these steps produces noise and consumes some time, resulting in broadening of peaks and a reduction in pulse throughput of the system.

Recently, instruments based on a digital signal processor (DSP) have been developed. The DSP combines functions of amplifier and ADC. To enhance the signal-to-noise ratio, the pulse obtained from the preamplifier is converted to triangular, trapezoid or quasi-trapezoid shape and the result is digitized directly to channel addresses. The shape of the pulse can be adjusted to fit the detector individually. Particularly, the duration of the pulse “flat top” can be set to compensate for the problems of detector charge collection and subsequent ballistic deficit. Also, the pulse rise and fall time can be set. These features together with the elimination of separate amplifier and ADC reduce noise in the measurement system, with a consequent improvement in resolution. In addition, the throughput of the measurement system rises, because the pulse shaping requires less time than with the traditional pulse shaping electronics. The DSP can easily reach a throughput of 100,000 counts per second, which can only be matched by the best and most expensive amplifiers and ADCs. In the future, commercial DSP may also have the power to resolve the overlapping preamplifier pulses in real time.

6 γ-SPECTRUM ANALYSIS

6.1 Characteristics of the Spectrum

The analysis of a γ-spectrum is based on photo-peaks; the analysis software locates the peaks, determines the peak areas (counts) and thereafter calculates peak emission rates (counts per second corrected for detector efficiency), associates peaks with radionuclides, and calculates their activities. It is important to know if the activity of a radionuclide is above a statistical detection threshold. Therefore, the detection limits are usually determined during the analysis phase as well. Many software packages are available for performing spectrum analyses.

A typical γ-spectrum consists of many components. Most of the baseline in the spectrum is formed by photon scattering. Around the region of 150–300 keV, the backscattered radiation is manifested as a broad peak or an increased baseline. The peaks in the spectrum have many origins (Figure 13).

6.2 Calibrations

Four different calibrations have to be performed for γ-spectrometric measurements:

- energy calibration, i.e. channel vs. energy;
- efficiency calibration, i.e. γ-peak area and source activity relationship versus energy;
- shape calibration; i.e. peak shape versus energy;

Figure 13 Typical air filter spectrum containing normal natural radionuclides. Analysis software, such as Shaman, is designed to explain the origin of all photo-peaks, escape peaks, sum peaks, X-ray peaks and X-ray escape peaks.
• total efficiency calibration, i.e. total number of photons detected per source activity versus energy.

The high quality of the calibrations is of utmost importance, because all the analysis results rely on them.

6.2.1 Energy Calibration

Energy calibration must be performed before any other calibration or analysis procedure. The calibration represents the relationship between the MCA channels and the photon energies. The calibration procedure is quite straightforward because the resulting channel number versus energy plot is very close to a straight line. Energy calibration can be generated using knowledge of \( \gamma \)-energies contributing to spectral peaks (Figure 14). The energy calibration has to be recalculated periodically to maintain the correct energy-channel relationship. The amplifier gain tends to drift due to environmental reasons (temperature, etc.), although this can be compensated during spectrum acquisition using digital stabilization (section 5.4).

6.2.2 Efficiency Calibration

6.2.2.1 The Empirical Calibration Method

The empirical calibration method is a straightforward but laborious procedure. In the empirical method the calibration source resembles the actual sample, with the chemical composition and size being similar. Many \( \gamma \)-spectrum analysis programs support a semiautomatic process for the efficiency calibration. A fully automated procedure is also possible.\(^{139}\)

The calibration source is added evenly to the sample matrix. Self-absorption is taken into account only if the calibration source has the same density as the real sample. Otherwise self-absorption correction has to be introduced at the data analysis phase.

The calibration source is usually a liquid containing many isotopes. To prevent the effect of coincidence summing (section 6.6), the calibration sources have to be selected carefully. The best choice is to use single-line sources, such as \(^{241}\)Am and \(^{137}\)Cs (Appendix 1). The calibration liquid has to be diluted to a suitable concentration (dead time below 10\%), and it must be handled cautiously. Even a minor contamination of the detector or the shielding may disturb or prevent low-level sample analysis.

The calculation of the efficiency calibration curve is straightforward from the results of the measurements performed. Only the peak count rate, calibration source activity and photon branching ratio (obtained from the nuclear data) have to be taken into account. For example, if the \(^{137}\)Cs calibration source with activity of 10 kBq has been used, and the calibration peak count rate is 100cps, the efficiency at the energy of 661.7 keV (\(^{137}\)Cs) is 100/(10000 \times 0.85) = 0.0118. The measured calibration points are usually fitted to logarithmic polynomials, but this mathematical relationship between efficiency and energy has no firm theoretical background and does not help to understand the calibration. However, the log–log plot of the calibration data must form a straight line above 200 keV; any deviation from this line is an indication of erroneous calibration measurement.

6.2.2.2 The Semiempirical Calibration Method

The semiempirical calibration method requires that measurements are performed to generate one or more efficiency curves for a simple fixed geometry. Point sources with well-known activities (uncertainty <5\%) are placed in a predefined position at a distance larger than 10 cm from the detector end cap (this arrangement avoids problems with true coincidence correction, see section 6.6). The calibration is then performed with a small set of nuclides (Figure 15), such as \(^{241}\)Am (59.5 keV), \(^{57}\)Co (122.1 keV), \(^{137}\)Cs (661.7 keV) and \(^{60}\)Co (1173.2 keV, 1332.5 keV). To have more confidence in the result, more nuclides should be used; for example the calibration data points from \(^{85}\)Y (898.1 keV, 1836.1 keV) and \(^{141}\)Ce (145.4 keV) would be valuable additions to the measured efficiency curve. The activities of the nuclides should be between 5 kBq and 500 kBq and more than \(10^4\) counts should be acquired in each peak (to allow a counting error of <1\%). The point source measurements provide complete calibration curves for a wide energy range. Thereafter the final efficiency calibration curve is generated by software which
converts the measured efficiency curves to the geometry of interest (Figure 15). The computation involves a straightforward integration over the detector and sample materials. This method provides a means of taking into account variability of sample dimensions and density. However, it requires accurate information on the detector itself and on the surrounding materials, including the sample.

The calculated peak efficiency calibration must be verified with a sample comparison measurement using an HPGe detector with well-known characteristics. The overall inaccuracy of the efficiency curve is related to activity inaccuracies of the point sources; the method has a typical uncertainty of 5% over the energy range of 50–3000 keV. Reliable and validated software, such as Decca, is necessary for the success of the method.

The semiempirical calibration method is simple, reliable, and provides a way of obtaining calibration curves for different samples. This method should be chosen, whenever possible, avoiding awkward geometry-specific measurements that are prone to errors and contain a substantial risk for detector contamination. In the future, detector manufacturers may provide point source calibration curves for their standard detectors and software for the user-specific calibration needs.

### 6.2.2.3 The Computational Calibration Method

The computational calibration method includes Monte Carlo calculations and requires no measurement. All the calculations are performed using information about the geometry, the sample and the surrounding materials. The detector and the sample need to be described in detail; the window materials, the dead layer, the vacuum around the detector and the properties of the sample and its container are crucial information for the success of the Monte Carlo calculations.

Computational methods are likely to become increasingly important in the future as hardware and software capability improves, and as standard detectors with well-known characteristics become available. However, modeling of the pulse acquisition system is also warranted. Otherwise the overall uncertainty of the simulations is above 5–10%, which is unacceptable for operational use.

### 6.2.3 Peak Shape Calibration

Peak shape calibration is required for peak location and fixed-width peak area determination. For optimum performance, the peak location algorithm requires input of the width of the peak.

The simplest method for shape calibration is to calculate the fwhm directly from the data for a number of γ-peaks (section 3.1). Another method is to perform free-width peak fitting for selected calibration peaks.

This method requires that the γ-peaks are not part of a multiplet.

The peak width calibration is not sufficient for the determination of the shape of γ-peaks that have tails. If they are not properly taken into account, the peak area determination is inaccurate. The tailing parameters have a slight energy dependence. The tails in the γ-peak occur typically in the lower energy side (section 3.1). Sometimes, there can also be a tail in the higher end of the γ-peak as a result of high count rate problems, with pulse pile-up effects in the electronics.

In addition to normal photo-peaks, the spectrum contains other peaks. Sum peaks, single escape peaks, X-ray peaks, and the annihilation peak are slightly wider than the photo-peaks at the same energy. Such peaks should not be used in the generation of the calibration curve.

The spectrum analysis program has to construct a mathematical relationship between fwhm and energy. The following functions have been used for the shape calibration, Equations (24–27):

\[
y = a + bE \\
y = a + bE + cE^2 \\
y = a + b\sqrt{E} \\
y = a + b\sqrt{E} + cE + \cdots
\]
where \( y = \text{fwhm} \), and \( a, b \) and \( c \) are fitting parameters. None of these equations have any theoretical justification. The peak width is a smoothly increasing function of energy. Therefore, all of these equations seem to describe the data reasonably well, at least when justified by the naked eye. Equation (26) is used widely; it has, however, the inherent feature of falling off rapidly at low energies, overestimating at medium energies, and underestimating at high energies. Equation (27) corrects these shortcomings, and describes the data well, but it has the same drawback as the other equations; there is no interpretation for the fitting parameters that would refer directly to the quality of the equipment.

Equation (16) shows that the variances of charge production, charge collection and electronic noise are additive, but not the standard deviations. The variance of the charge production is proportional to the energy (Equation 5). The noise of the equipment is constant, independent of energy, and dominates the total resolution at low energies. It is not clear what function would describe the uncertainty of charge collection fortuitously; this effect is very small for modern detectors, particularly for detectors with small dimensions. To improve the quality of the fit, however, a correction factor proportional to \( E^2 \) could be used, if needed, for large detectors. Then, the fwhm would be described, as illustrated in Equation (28), by

\[
\text{fwhm} = \sqrt{a + bE + cE^2} \tag{28}
\]

and the curve fitting would be performed by the function (as shown in Equation 29)

\[
y = \text{fwhm}^2 = a + bE + cE^2 \tag{29}
\]

The components of the fwhm for charge production and noise are shown in Equations (30) and (31) as

\[
\text{fwhm}_p = \sqrt{bE} \tag{30}
\]

\[
\text{fwhm}_n = \sqrt{c} \tag{31}
\]

In addition, in Equation (32), the constant \( b \) is constrained according to Equations (5), (18) and (30) as

\[
b = 2.355^2FW = 5.546FW \tag{32}
\]

The acceptable values of \( b \) are limited by \( F(0.058–0.12) \) and \( W(2.96\text{keV}) \). The noise component \( \text{fwhm}_n \) could be estimated directly (Equation 21). Measurement is not necessarily a practical approach.

Similarly, the contribution of charge collection could be described, Equation (33), by

\[
\text{fwhm}_c = \sqrt{cE} \tag{33}
\]

The interpretation of \( c \) is not necessarily meaningful. A fit without the second-order term \( (c = 0) \) may give an estimate for \( b \) that is somewhat too large. This is an indication of imperfect charge collection in the detector. The correction term \( (c > 0) \) improves the fit and reduces the value of \( b \) to an acceptable range.

Briefly, in curve fitting, there are two options which have theoretical justification:

1. apply Equation (29) with \( c = 0 \); if the fit is bad, include second order term \( (c > 0) \);
2. apply Equation (29) with constraints for \( a, b \) and \( c \); the value of \( a \) is a constant or it may be constrained to a range given by the error estimate of the noise measurement; the value of \( b \) should be constrained to a range of \( 0.94–2.0\text{keV} \); \( c \geq 0 \).

Typical behavior of the peak width can be seen in Figure 16.

6.2.4 Total Efficiency Calibration

Total efficiency calibration is required for coincidence correction (section 6.6). This calibration curve represents the relationship between all the photons detected in the detector and the source activity. The calibration depends on source geometry and source detector distance. As most of the photons are detected at the Compton continuum, the surrounding material also has an effect on this calibration. Only single-line emitters should be selected. Emitters with two lines can be used but the mean energy of the \( \gamma \)-peaks has to be selected for the calibration energy.

![Shape calibration](image)

**Figure 16** Peak widths of a typical \( \gamma \)-spectrum. A square root polynomial of degree 3 is fitted to the data (Equation 27). Equation (28) gave exactly similar fit (difference less than 0.02 keV). \( \text{fwhm}_n = 0.92\text{keV} \) (Equation 31) and \( F = 0.11 \) (Equation 32). The separate dot represents the width of the annihilation line (511 keV). The annihilation line is about twice as broad as the \( \gamma \)-peaks at the same energy.
6.3 Peak Location

The most common method of finding $\gamma$-peaks in the spectrum is to calculate the smoothed second difference and to determine if there is a peak above the search threshold.\(^{(21)}\) Peak detection is based on signal-to-noise ratio of peak to baseline, and the result is presented as standard deviations. In the peak location process, one also has to be aware of the peak shape which is specific to the detector used. The peak width is the essential parameter. The shape of the filter varies in different applications. Other peak location methods are fast Fourier transformation for locating the nominal values in the spectrum and a correlation method based on integer summing.\(^{(3,6)}\)

Because the data are discrete pulse counts with stochastic fluctuations, statistical criteria have to be applied to the peak search. The generalized second difference, illustrated by Equation (34)

$$dd_i = \sum_{j=-k}^{k} c_j n_{i+j}$$  \hspace{1cm} (34)

and its standard deviation are calculated for each channel $i$ as shown in Equation (35):

$$sd_i = \sum_{j=-k}^{k} c_j^2 n_{i+j}$$  \hspace{1cm} (35)

where $n_{i+j}$ is the pulse count at channel $i + j$, and $c_j$ is a constant multiplier which can be obtained using different filters, such as a Gaussian function with a distribution similar to the $\gamma$-peak.\(^{(5,6,18,19)}\) Standard deviation of pulses at each channel $n_i$ is assumed to be the square root of $n_i$. If the $\gamma$-peaks have pure Gaussian shape, with standard deviation $\sigma$, on a constant baseline $b$, then (Equation 36)

$$n_{i+j} = a \exp \left( \frac{-(i+j)^2}{2\sigma^2} \right) + b$$  \hspace{1cm} (36)

where $a$ is a constant. The peak is located at the channel where the smoothed second difference has its negative minimum. This is the same channel where the first difference changes the polarity from positive to negative.

The peak search threshold is a statistical limit the peak area has to exceed for its acceptance. The peak significance tells approximately how many standard deviations the peak area is above the background area defined by the baseline. The search algorithm finds a peak if its significance is above the selected peak search threshold. Usually this parameter has a value of 3.0 "sigmas". A different set-up between 2.5–10 may be more appropriate in special applications. A good peak search algorithm can disregard too narrow peaks and Compton edges because of their incorrect shape.

A library oriented peak search is useful for radionuclides of particular importance. In this method, peaks are inserted to the spectrum at the energies of interest. Thereafter, statistical tests are used to decide whether the peaks are really present.

6.4 Peak Area Determination

The simplest way to determine the $\gamma$-peak area is to sum the channel contents over the peak and to subtract the baseline by taking into account the baseline level on both sides of the $\gamma$-peak. The method is feasible for nonoverlapping $\gamma$-peaks.

An accurate method for peak area determination is to fit a shape function into the spectral data. The peak shape is often Gaussian but many programs use tailing parameters to improve the fit.\(^{(18)}\) The baseline below the peak is either linear, parabolic, or a step function. There are several methods of describing the step function below the $\gamma$-peak. For normal $\gamma$-peaks the step is higher on the low-energy side. For the escape peak the step can be higher on the high-energy side of the peak.

Incomplete charge collection, charge trapping and recombination, electronic noise and random summing at high pulse rate tend to broaden the $\gamma$-peak. The tails, particularly at the low energy side of the $\gamma$-peak, have to be taken into account during peak area determination.

In general, the fitting procedures use the least-squares techniques to minimize the weighted square sum of the fitting residuals (Equation 37):

$$\chi^2 = \sum_{i=k-a}^{k+m} \frac{(n_i - f_i)^2}{n_i}$$  \hspace{1cm} (37)

where $i$ is the channel number; $k$ is the center channel of the peak; $a$ and $m$ are the limits for the fitting interval; $n_i$ is the counts, and $f_i$ is the fitted function at the channel $i$.

The baseline of the spectrum should be included in this fitting procedure. The minimized function is calculated as follows in Equation (38):

$$\chi^2 = \sum_{i=k-a}^{k+m} \frac{n_i - b_i - \sum_{j=1}^{q} f_{ij}}{z_i}^2$$  \hspace{1cm} (38)

where $b_i$ is the baseline function, $q$ number of peaks in the fitting interval, and $z_i$ is the weighting factor (usually $n_i$ or smoothed value of $n_i$).

Fitted functions differ in different software. The following possibilities are quite common:

- peak shape can be either Gaussian or Gaussian with exponential tails.
the baseline below the peak can be either linear, parabolic or step function;

- the step function may have various definitions which have been developed using the data itself, not the physical phenomenon producing the data.

The fitting procedures vary as well:

- linear fixed-width (peaks are not allowed to move during the fitting procedure);
- nonlinear fixed-width (peak position and height are allowed to move during the fitting procedure);
- free-width (there is no limitation on peak width, the peak width is compensating fluctuations caused by uncertainties in the peak width calibration and overlapping peaks);
- mixed (the user can select different approaches for each peak during the interactive peak fitting procedure).

The fixed-width peak fitting procedure requires that the peak shape calibration is properly set up for the spectrum prior to the analysis. The free-width fitting procedure does not need this information, but on the other hand, is not using all the information available to treat the overlapping peaks and, therefore, the error estimates are increased due to the poorly-shaped peaks. Fixed-width fitting makes it possible to resolve highly complex multiplets (Figure 17).

Residual peak search is possible only for the fixed-width fitting procedure. The missing peak can be inserted if during the fitting procedure the analysis software, or the user in the interactive fitting mode, notices a missing component by checking the residual between the fitted curves and the actual data.

Good software allows to view the residuals simultaneously with the fitted peak. High residuals (above 4 sigma) are an indication of a missing peak. The residuals can also reveal inaccuracies in the peak shape calibration, particularly if the peak tails are omitted for detectors which clearly have non-Gaussian peak shapes. Other visible structures, such as “residual waves” are an indication of incorrect peak width calibration.

6.4.1 Background Subtraction

Some radionuclides, such as $^{40}$K, $^{232}$Th, $^{235}$U and $^{238}$U, commonly contribute to the background of the spectrum. If these nuclides are of interest in the analysis, the constant background has to be subtracted from the calculated activity. Subtracting the two spectra is bad practice in the statistical sense because of the merging two different distributions. The subtraction therefore has to be done after the peak area determination. The net area $A_n$ of the peak is shown in Equation (39) as

$$ A_n = A_s - \frac{T_s}{T_b} A_b $$

where $A_s$ is the peak area of the $\gamma$-spectrum of interest; $A_b$ is the peak area of the background and $T_s$ and $T_b$ are the corresponding live measuring times. This approach assumes that the same detector and the same electronics set-up are used both for the background and the actual sample acquisition. The corresponding error for this
reduced peak area is illustrated in Equation (40)

\[
\Delta N = \Delta S^2 + \left( \frac{T_s}{T_b} \Delta B \right)^2
\]

(40)

where \( \Delta S \) and \( \Delta B \) are the errors of the areas in the actual measurement and in the background measurement, respectively.

### 6.5 Minimum Detectable Activity

The existence of a \( \gamma \)-peak has a probabilistic character; so the probability level at which the selected radionuclide or \( \gamma \)-peak exists has to be defined. In \( \gamma \)-spectrometry this is often calculated by the method of Currie,\(^{22}\) as explained below. This method is based on statistical considerations only, and calculations use strict statistical rules applied to the properties of the measured spectrum. The analyst selects a probability level which all the peaks have to fulfil for reliable detection. The resulting minimum detectable activity (MDA) is used to discriminate against calculated activities less than this MDA value.

Consider a hypothesis that a peak is observed at a certain place in the spectrum. Let \( \alpha \) be the probability that this observation is spurious. Then \( 1 - \alpha \) is the probability that this observation is correct. The critical limit or the decision limit is the area of the \( \gamma \)-peak for its detection with a given probability level. It is defined as illustrated in Equation (41)

\[
L_C = k_\alpha \sigma_0
\]

(41)

where \( k_\alpha \) is the abscissa of the standardized normal distribution at the selected probability level \((1 - \alpha)\), and \( \sigma_0 \) is the standard deviation of the net signal when its expected value equals zero. Consider now that this observation procedure is already performed. Let \( \beta \) be the probability that a peak is not seen at the selected energy, but there still is a peak. When a nuclide detection is warranted at the selected probability level, the nuclide activity has to exceed the detection limit, shown in Equation (42), of

\[
L_D = L_C + k_\beta \sigma_D
\]

(42)

where \( k_\beta \) is the abscissa of the standardized normal distribution at the selected probability level \((1 - \beta)\), and \( \sigma_D \) is the standard deviation associated to this limit. The variance of the net signal illustrated in Equation (43), is

\[
\sigma^2 = \sigma_{s+b}^2 + \sigma_B^2
\]

(43)

where \( \sigma_{s+b} \) is the standard deviation of the gross signal and \( \sigma_B \) is the adjacent standard deviation of the baseline.

When there is only background present, the expected value of the signal is zero, giving in Equation (44):

\[
\sigma_0^2 = 2\sigma_B^2, \sigma_B = \sqrt{B}
\]

(44)

and Equation (45)

\[
L_D = L_C + k_\beta \sqrt{L_D + \sigma_0^2}
\]

(45)

Finally, \( L_D \) can be solved using Equations (41), (42) and (45) as shown in Equation (46):

\[
L_D = L_C + \frac{k_\beta^2}{2} \left( 1 + \frac{4}{k_\beta^2} \right) L_C + \left( \frac{L_C}{k_\alpha} \right)^2
\]

(46)

With the selected probability level of 95% for both \( \beta \) and \( \alpha \) the detection limit can be calculated. In this case \( k_\alpha \) and \( k_\beta \) are 1.65. If there are no interfering peaks at the same energy range, the decision limit \( L_C \), illustrated in Equation (47), is:

\[
L_C = k_\alpha \sqrt{2} \sigma_B = k_\alpha \sqrt{2B} = 1.65 \sqrt{2B} \approx 2.3 \sqrt{B}
\]

(47)

At 95% confidence level \((k_\alpha = k_\beta = k = 1.65)\) the detection limit \( L_D \), illustrated in Equation (48), is

\[
L_D = k^2 + 2L_C = 2.71 + 4.65 \sqrt{B}
\]

(48)

At 99% confidence level \((k = 2.33)\) the detection limit, illustrated in Equation (49), is

\[
L_D = 5.42 + 6.59 \sqrt{B}
\]

(49)

If there is an interfering \( \gamma \)-peak, the standard deviation is as shown in Equation (50)

\[
\sigma_0 = 2B + \left( \frac{T_s}{T_b} \right) A_b + \left( \frac{T_s^2}{T_b^2} \right) A_b
\]

(50)

where \( A_b \) is the area of the background peak (obtained using long-term background data).

The sampling and the sample preparation process also have an influence on the detection limit. Some of the nuclides may be lost or removed before counting. In air sampling, for example, the particle collection efficiency may be significantly below 100%. However, if the sampling is optimized, i.e. the system has short tubes without any bends, and the filter material is of good quality, the losses of small particles (\(<10\mu m\)) are negligible.

### 6.5.1 Baseline Width Selection for Minimum Detectable Activity Calculations

The baseline definition in the original Currie formulas were intended for a single channel analyzer.\(^{22}\) Therefore, the method expects the baseline to cover exactly the
counts that are “below” the peak. Broadening the baseline width too much increases MDA to unrealistic values.

The optimum baseline width below the $\gamma$-peak is $\pm 1.4\sigma$, as derived analytically by optimizing the signal-to-noise ratio. Only 83% of the peak area is included within $\pm 1.4\sigma$ (assuming Gaussian peak). Therefore, the baseline should be extended by a factor of 1.193 to cover the whole peak baseline area (Figure 18). As a result, the optimum and justified baseline width is $\pm 0.71$ fwhm (Equation 18).

For a typical environmental sample, MDA in a $\gamma$-spectrum is about 10 mBq for nuclides that emit photons of high abundance, such as $^{137}$Cs. An example of the results of the MDA calculations is given in Table 6 for an air sample. The selection of the counting time is of crucial importance for the optimum detection capability. In principle, several spectra should be saved during the data acquisition for optimizing the MDA for different nuclides with different half-lives.

The surety of peak existence can be categorized according to the peak significance, which is defined as the peak area divided by $L_D$ according to the definition in Equation (48) with probability level of 95%. An uncertain or “gray” zone can be defined as $(0.5 - 1.4) \times L_D$. A found peak can be regarded as a false peak (type I error), if its area is below the lower limit, which in fact is $L_{C,a}$, as defined in Equation (47) at the probability level of 95%.

The peak can be regarded as a true peak if its area is above the upper limit, which in fact is $L_D$ at 99% confidence level, as defined in Equation (49). The analysis of the gray peaks, particularly if they are associated to radionuclides, requires special attention from the analyst. The gray zone may have to be enlarged or diminished according to the application and software; the areas of small peaks and $L_D$ vary according to the algorithm used.

### 6.6 Radionuclide Identification and Activity Calculations

After the peak areas have been calculated, and their emission rates are determined using the efficiency calibration, it is time to identify the radionuclides contributing to the $\gamma$-spectrum. This involves qualitatively deciding which nuclides are present and thereafter quantitatively determining their activities. All identification procedures start by matching the observed peak energies with energies of photon transitions by known radionuclides. This gives a preliminary set of candidate nuclides, among which one hopefully has a subset forming the correct solution. There are three basic approaches for resolving the preliminary candidate set:

1. Calculate the activity of each candidate nuclide based on the $\gamma$-peak of largest abundance that is not interfering with other candidate nuclides. In this case the analyst has to select the appropriate $\gamma$-lines specific to the radionuclides of interest.

2. Form a matrix of all candidate nuclides and spectrum peaks with branching ratios as coupling constants and minimize it in the least-squares sense. This yields activity estimates for all included candidate nuclides. Normally precalculation discrimination of candidates is required, which can be based on simple rules taking into account the energy tolerances, other $\gamma$-lines of the radionuclides and the decay periods.

3. Use an expert system approach using a comprehensive set of both heuristic rules and objective quantitative information on the measurement and radionuclides involved to reduce the set of candidate nuclides as much as possible. Afterwards, calculate the activities using the methods above.

Parent–daughter relationships have to be taken into account for radionuclides from the same decay chain. Otherwise, short-lived nuclides produced by longer living parents would be erroneously discarded or the activity calculation would be incorrect.

Least-squares minimization of the candidate matrix is used to solve the problem of interfering radionuclides (Table 7). In the candidate matrix the associated nuclides with unknown activities are in one dimension and the
Table 6  Typical detection limits in air sampling for a high-volume sampler.\(^{(23)}\) MDA is calculated from the Currie equation (Equation 48) using baseline width of 1.42 times the fwhm.\(^{a}\) MDA (Bq) is converted to MDC (Bqm\(^{-3}\)) using the total amount of air (22500 m\(^3\)) that passed through the filter during the 24 hour sampling period. The sample was counted in Williams geometry (Figure 10a) using a 40% p-type HPGe.

\(^{a}\) The original calculations were performed using baseline width of 2.5 fwhm.

Table 7  Activity calculation for interfering radionuclides by least-squares minimization. Some peaks in the spectrum may be associated to several radionuclides but most of these nuclides have multiple \(\gamma\)-lines. Therefore, the spectrum can have “subsets” of peaks which have correlation with other peaks. The fraction each nuclide is explaining of each peak has correlation with other nuclides. Labels X in the present hypothetical example refer to the radionuclides contributing to the peaks involved. Numerical least-squares minimization is the most practical way to solve this problem, i.e., the computer finds the optimum shares for each radionuclide. Modern software packages are able to perform this calculation\(^{(17,24,25)}\).

emission rates of the found photo-peaks are in the other dimension; the branching ratios of the respective nuclide transitions are the coupling constants. The coupling matrix and the emission rate vector are weighted by the errors of the peak emission rates.

The construction of the candidate matrix is straightforward, but calculating the matrix inversion is not always a simple task\(^{(17)}\). The matrix can be underdetermined, overdetermined, or even completely singular. Therefore strong numerical methods, such as singular value decomposition (SVD), have to be used\(^{(28)}\).

Correction for the radionuclide decay has to be included in the activity calculations for all the phases of the sample preparation and acquisition. The correction term for the decay during counting is illustrated in Equation (51):

\[
C_C = \frac{\lambda t_c}{1 - e^{-\lambda t_c}}
\]  

where \(t_c\) is counting time and \(\lambda\) is the decay constant.

The correction term for the waiting before the data acquisition, i.e. the decay correction during the waiting time \(t_w\), is illustrated in Equation (52):

\[
C_w = e^{+\lambda t_w}
\]  

During the sampling time \(t_s\) some of the radionuclides in the sample have decayed. The correction term is
illustrated in Equation (53):

\[
C_s = \frac{\lambda D}{1 - e^{-\lambda t}} \quad (53)
\]

For the air filter sample, the average activity concentration \( a \) (Bq m\(^{-3}\)) of a nuclide is shown in Equation (54)

\[
a = \frac{\lambda D A_w}{(1 - e^{-\lambda t}) V_{\text{tot}}} \quad (54)
\]

where \( V_{\text{tot}} \) is the total volume of air and \( A_w \) is the activity at the end of the sampling.

Self-absorption correction is essential if the dimensions and the density of the samples vary. The photons are absorbed in the sample matrix in different ways. This uncertainty is a source of fluctuations in the \( \gamma \)-peak areas. If the efficiency calibration is based on the computational methods, an individual efficiency curve can be calculated for each sample according to the dimensions and the density of the sample.\(^{14,15}\) The self-absorption correction is of particular importance in the applications where accurate nuclide activity ratios are required.

Background matrix correction is similar to the self-absorption correction but carried out for true background nuclides present in the structures of the measurement room. An approximate correction function can be estimated a priori\(^{17}\) or more accurately from the background measurements.

Coincidence summing is an important phenomenon at high-count rates or close geometries. True coincidence summing occurs when two or more \( \gamma \)-transitions in a decay scheme are in cascade and the half-lives of the intermediate states are shorter than the time resolution of the detector. Therefore, the cascade photons seem to create too small peaks, and furthermore, a coincidence peak is formed at the energy equal to the sum of the component energies. In some cases, when the intermediate half-lives are favorable, both photons can be rejected by the PUR or active Compton suppression hardware.

The calculation of the coincidence correction is straightforward.\(^{6,26,29}\) Let us consider a simple decay scheme with two photons in cascade (Figure 19). If no photon summing would occur, the ideal peak count rate \( S_{21}^i \) for the transition from level two to level one would be affected only by the nuclide activity, the peak efficiency of the detector and the branching ratios \( (x_{21} \text{ and } N_2) \). However, because of photon summing, the observed count rate \( S_{21} \) is as illustrated in Equation (55)

\[
S_{21} = S_{21}^i(1 - e_{1,10}) \quad (55)
\]

where \( e_{1,10} \) is the total efficiency of the detector in the counting geometry involved for the transition from level one to level zero, i.e. \( e_{1,10} \) is the overall probability that this photon is counted. The coincidence summing correction is defined in Equation (56) as

\[
C_{21} = \frac{S_{21}^i}{S_{21}} = \frac{1}{1 - e_{1,10}} \quad (56)
\]

Similar but more complex correction factors can be derived for other transitions and for different decay schemes.\(^{6,26,29}\) The correction factors vary between 0.4 – 2.3 and they depend on the source–detector distance.\(^{26}\) At distances larger than 15 cm, no correction is needed.

The theory of coincidence correction is well known. Therefore, it is astonishing that only very few commercial software packages are able to treat coincidence summing effects.

Random summing occurs when the count rate is sufficiently high for two photons to interact simultaneously with the detector. Random summing is not a problem in low-level counting.

### 6.6.1 Unidentified Peaks

If a spectrum contains unidentified peaks after a routine analysis, the following procedures could be implemented:

1. Check if the peak is a single or double escape peak (511 keV or 1022 keV below a large \( \gamma \)-peak above 1022 keV).
2. Check if the peak is a result from random summing by two large peaks at low energies.
3. Check if the peak comes from a nuclide which is in parent–daughter relationship with nuclides already identified.
4. Check if the peak could be associated to cosmic radiation (139.7 keV of $^{75m}$Ge for example), or to other external origin.
5. Check if the peak could be associated to X-ray escape (10 keV below a large photo-peak).
6. Check other nuclide candidates at the same energy. Start the procedure from the highest unidentified peak. The energy look-up tolerance could be widened to account for possible errors in the energy calibration.

6.6.2 Rule-based Nuclide Identification

Sophisticated expert systems, such as Shaman,\textsuperscript{(17,25–27)} have several advantages compared with classical, algorithmic identification procedures:

1. Comprehensive radionuclide library. No tailoring of the library is necessary because the expert system can use a variety of heuristic rules to reduce the number of candidate nuclides during identification. This makes it possible to use a library of all known radionuclides and transitions (80,000 $\gamma$- and X-ray lines), which in principle gives the system the ability to correctly identify any sample composition. Classical identification algorithms get into trouble with spurious identifications if the library is too large (more than 1000 $\gamma$-lines).

2. Rule-driven identification process rather than predetermined algorithm. Management of knowledge and the handling of various complex phenomena is straightforward, including

(a) decay chain handling and various activity corrections;
(b) nuclide-specific rules taking into account production modes of nuclides;
(c) handling of escape and coincidence sum peaks;
(d) rules specific to the MDA calculations;
(e) peak-specific rules based on MDA, peak width, and peak significance, for example, and
(f) sample and measurement-specific rules for including the analyst’s specific knowledge of the measurement (nuclides that can or cannot be present, etc.).

3. Versatile and yet conservative rule base. By correctly setting the expert system parameters, the system can be tuned to the identification problem precisely, which has not generally been possible for traditional identification methods.

The identification result by an expert system is excellent because of advantages of the combined heuristic rules and the complete nuclide library. In a typical $\gamma$-spectrum, 99% of the $\gamma$-peaks can be identified routinely without any human interference.\textsuperscript{(25)} Combination of rule-based identification, robust activity calculation and high-quality quantitative analysis with strong multiplet resolving capability results in the competent $\gamma$-spectrum analysis package.

7 IN SITU $\gamma$-SPECTROMETRY

7.1 Principles of In Situ Measurement

$\gamma$-Spectrometry performed in the environment is a rapid method for detecting and quantifying radioactivity in the air and in the ground. Large areas can be surveyed rapidly after a nuclear accident using portable equipment in vehicles, helicopters or airplanes. Combining of concentration or deposition results with satellite navigation data provides a powerful tool for the assessment of radiation hazard.

The term in situ $\gamma$-spectrometry has been adopted for measurements that are performed close to the source in the environment. This technique has been used since the 1960s for uranium exploration and environmental monitoring. The reactor incident at Three Mile Island in 1979, and the Chernobyl accident in 1986, convinced radiation safety authorities and other organizations to adopt quick and reliable methods for the determination of radionuclides, and in situ $\gamma$-spectrometry is now used widely for estimating levels of environmental contamination.

Besides providing prompt results on radiation hazard at the early stage of a nuclear accident, the in situ method reduces data variability, because soil sampling with later laboratory measurement is prone to nonrelevant spatial source variations. The field of view is particularly large in airborne measurements. In fall-out mapping, the depth distribution of the radionuclides may be unknown. Various assumptions have to be made which, in turn, are the main source of uncertainty in the result. Therefore, some ground or air sampling should be performed to verify the in situ results.

The theory of in situ $\gamma$-spectrometry was developed by Beck et al. in 1972.\textsuperscript{(30)} The basic problem is to determine the ratio between the full energy peak count rate $N_t$ and the source term $S_x$, as illustrated in Equation (57):

$$\frac{N_t}{S_x} = \frac{N_0}{\phi} \frac{N_t}{N_0} \frac{\psi}{S_x}$$ (57)
where $N_0/\psi$ is the photo-peak efficiency (Figure 20), i.e. the full-energy peak count rate ($s^{-1}$) per unit fluence rate ($s^{-1} m^{-2}$), for photons arriving from the axial direction of the detector ($\theta = 0$). $N_f/N_0$ is the angular correction factor that takes into account that the fluence is not normal to the detector face. $\phi/S_x$ is the ratio between the fluence rate and activity concentration, expressed as activity per unit area $S_a$ (Bq m$^{-2}$), activity per unit mass $S_m$ (Bq kg$^{-1}$) or activity per unit volume $S_v$ (Bq m$^{-3}$). $\phi/S_x$ does not depend on the properties of the detector and can be calculated for various geometries.$^{(20,31,32)}$

7.2 Ground-level $\gamma$-Spectrometry

7.2.1 Radionuclides in Terrain

The term $N_f/N_0$ in Equation (57) depends on the detector characteristics and the source geometry. It is computed as a weighted average of the normalized full-energy peak count rate per unit fluence rate as a function of angle, $N_f(\theta)$, over the fluence rate distribution.$^{(30)}$ The sensitivity of the detector is maximized if it faces downward ($\theta = 0$). Sometimes this might be impractical, particularly in mobile measurements.$^{(33)}$ The arrangement of detector facing upward with the dewar underneath reduces peak count rates because the dewar attenuates photon fluence from the ground underneath. Because the angular distribution of the fluence is peaked toward the horizontal direction, however, the total efficiency reduction is only a few percent for surface distribution of activity, and 10–20% for uniform source distribution.$^{(34)}$

If the detector chosen for the in situ measurements has equal length and diameter ($L/D = 1$), it may be possible to neglect the angular correction factor. In this case the detector should be calibrated using photon fluence from the side-wall direction ($\theta = 90^\circ$). Angular correction is necessary for a detector that is installed in a complex surrounding, for example inside a vehicle.

The source distribution has to be known or a reasonable approximation has to be used for the determination of the radionuclides in the ground. The radionuclides are usually assumed to have homogeneous concentration in the horizontal plane, but the depth distribution can vary. The natural radionuclides, $^{40}$K and the progenies of $^{238}$U and $^{232}$Th, often have a uniform concentration, whereas man-made radionuclides may have an exponential concentration profile. Fresh fallout is a thin layer on top of the ground. The uncertainty analysis of the in situ $\gamma$-spectrometry has shown that most of the error of the method is related to the depth distribution of the radionuclides in the soil rather than to detector characteristics, counting statistics or other measuring parameters.$^{(35)}$

To compute $\phi/S_x$, an exponential model for the source depth profile is widely used.$^{(31)}$ This method has only one parameter, the relaxation mass per unit area ($\beta$) for describing the real nuclide distribution. In recent fallout $\beta$ varies between 0.1 and 3 g cm$^{-2}$, but it can be up to 20 g cm$^{-2}$ for aged events (>10 years). Fluence rates in air at a height of 1 m above ground are available for natural radionuclides distributed homogeneously and for man-made nuclides as a function of $\beta$.$^{(31)}$ This information together with the calibration data allows calculating the peak response of the detector ($s^{-1}$ per kBq m$^{-2}$) for various nuclides (Figure 21).

The MDA per unit area is almost similar for radionuclides with equal decay yield. The weaker attenuation of high-energy photons is compensated by a lower peak response of the detector (see Figure 20). $^{131}$I or $^{137}$Cs contamination below 0.1 kBq m$^{-2}$ can be detected with a counting time of only 30 min (22% HPGe)$^{(31)}$.

7.2.2 Radionuclides in Air

In situ $\gamma$-spectrometry of airborne radionuclides provides many advantages that are most useful at the early stages of a nuclear accident. The results are immediately available and no sampling is needed. Detection of Xe isotopes is part of the measuring procedure; it is not a separate complex task (noble gases are the major source of external exposure in some accident scenarios).
In a nuclear emergency, the count rate may be so high that a counting period of a few tens of seconds can give adequate results. Data acquisition is easy to perform in short consecutive sequences; spectrum analysis and report generation can also be automated and performed in a few seconds.

Radionuclide concentration in air is a complex dynamic quantity that may change in short intervals. Far away from the source, the plume is usually wide enough to assume a simple geometry. The computation of $\psi/S_v$ is a straightforward task for an infinite slab plume.\(^{(20,31)}\)

The airborne contamination can be monitored with a detector that has no shielding. This approach is practical when the goal is to detect the presence of airborne man-made activity rather than to quantify the concentrations. Often the airborne activity produces in a few hours a deposition that generates a larger fluence rate than the cloud itself. For quantitative concentration estimates, the side walls of the detector should be shielded. The accuracy is further improved if the shielding has a lid for background measurements.

The isotopes of iodine, \(^{131}\)I, \(^{132}\)I, \(^{133}\)I, are the major inhalation hazard in a nuclear reactor accident. The inhalation exposure of the population may require countermeasures at a concentration level above 1000 Bq m\(^{-3}\). The in situ $\gamma$-spectrometry can detect contamination as low as 1–10 Bq m\(^{-3}\) in 10–30 min.\(^{(20,31)}\)

### 7.3 Airborne Spectrometry

#### 7.3.1 Ground Survey

Gamma-rays penetrate up to several hundred meters in air. Airborne survey of the environment is possible at an altitude of 100 m (or even 300 m), although a lower altitude of 30–60 m is more suitable for detailed radionuclide mapping (Table 8). The equipment must have the capability to measure at short intervals. In some applications, such as geological survey and search of lost or stolen radiation sources, the spectra acquisition time is about 1 s, whereas to reduce data volume for fallout mapping a longer counting period of 10–60 s would be more appropriate.

Low-resolution $\gamma$-spectrometry with large NaI crystals (volume >10 L) has a high sensitivity. The count rate from a 25 L NaI array is typically 50 times larger than from a 100% HPGe detector (volume ratio). However, the superior energy resolution of the HPGe detector provides reliable peak quantification and unambiguous nuclide identification for complex spectra. Therefore, mobile high-resolution $\gamma$-spectrometry is the only tool that can produce reliable nuclide-specific fallout maps immediately after a nuclear accident. Low-resolution spectrometry is useful at the later phases of the accident when most of the short-lived nuclides have decayed or in accident scenarios where only one or a few nuclides are involved.

The mobile measurements are much more difficult to perform than the laboratory measurements. The monitoring equipment has to be operated in harsh conditions where factors such as temperature or vibrations may interfere. Furthermore, the coordinates have to be recorded and attached to the measured spectra. The amount of data produced can be as large as 100 Mbytes per hour. Special software is needed to analyze the data and to produce nuclide-specific maps on the area searched.\(^{(36)}\)

Since the Chernobyl accident, several countries, particularly in Europe, have created mobile units that can perform the data acquisition and analysis promptly.\(^{(37)}\) The detection limits of airborne surveys are far below safety limits applied for the protection of the public (Table 9). Recent developments in detector manufacture have provided HPGe detectors with a large diameter (>80 mm). These detectors, which are planar rather than coaxial (section 4.1), reduce detection limits drastically, particularly for low-energy nuclides. Such a mobile system is very powerful in safeguard measurements, either in national or in international applications.

7.3.2 Tracking of a Radioactive Plume

Determination of nuclide-specific concentrations within a plume is difficult using in situ \( \gamma \)-spectrometry. The concentration pattern is a complex three-dimensional distribution which changes continuously with meteorological conditions. However, in situ spectrometry is useful for locating the radioactive plume and for identifying the release nuclides. Detection of the radioactive cloud before the nuclides deposit to the ground gives more time for possible countermeasures.

Two different scenarios should be addressed. The plume may have clear boundaries because the source is near, or the plume has traveled a long distance and has dispersed in the atmosphere over a large frontier. A helicopter is useful for the close source studies, whereas a fixed-wing aircraft is preferable for a large area survey. The detection system could have an HPGe detector and two NaI crystals separated by lead shielding. The NaI-detector system provides information on whether the helicopter or the aircraft is over the plume, below the plume, or within the plume. Besides plume detection, it is possible to determine the axis, the boundaries and the height of the radioactive cloud.

A rough quantitative estimate of the release may be possible.\(^{38}\) However, more realistic goals for the flying team are plume detection, key nuclide identification (iodine) and sampling for later laboratory analyses.

8 QUALITY ASSURANCE SYSTEM

A quality assurance system is intended to guarantee the high quality of the products and services. Repeated measurements and analyses must produce the same, correct and reliable results. Anomalous results must be recognized in all circumstances. Furthermore, the means to control the whole chain of custody of the samples provide confidence in the overall analytical capability.

Any laboratory seeking external contracts will be expected to have appropriate accreditation. Comprehensive guidance to the accreditation process is provided by the national accreditation bodies, such as the National Institute of Standards and Technology (NIST) in the USA or the National Measurement Accreditation Service (NAMAS) in the UK. The process itself may take a long time, including development of quality requirements, their implementation, preparation of quality documentation, training, and internal and external audits. Although a laboratory would not seek any formal certificate, it is worth setting up a tailored quality assurance system applying international standards, such as ISO 9001 or ISO 17025.\(^{39,40}\)

8.1 Standards and Procedures

The quality assurance system sets requirements for the management and the technology. The international and national standards are an excellent support for developing the requirements and the procedures. The management requirements\(^{40}\) address the following points:

- organization
- structure of the quality system
- document control
- request, tender, and contract review
- subcontracting services
- purchasing services and supplies
- services to the clients
- complaints by the clients
- control of nonconforming work
- corrective action
- preventive action
- records
- internal audits and
- management reviews.

The technical requirements and procedures are intended to verify that the instruments are working properly, nuclear data are valid, standards are fit for the purpose and are traceable to international standards, and the spectrum analysis is correct. High quality is achieved if the measurement and analysis are performed according to validated and well-documented standard procedures. Any operational change must be properly validated before adoption to routine use.

The same set of most recent and validated nuclear data should be used in all operations of the laboratory. Changes must be documented. The International Atomic Energy Agency (IAEA) provides a small well-evaluated data set that is useful for energy and efficiency calibrations.\(^{41}\) The National Nuclear Data Center at Brookhaven National Laboratory, USA, maintains an Evaluated Nuclear Structure Data File (ENSDF). Appendix I is a subset of this file for radionuclides that are of importance in environmental \( \gamma \)-spectrometry.
High-quality data is also available through the Internet (see, for example, http://www.fysik.lu.se/nucleardata/).

The accuracy of the measurements depends on the quality of the calibration standards. The calibration sources should be purchased from accredited laboratories that can demonstrate traceability to a national standard. In the past, calibrations were performed, and are often still performed, in the geometry that mimics the sample dimensions and density. This kind of work requires calibrated solutions, is difficult to carry out (dilutions), is prone to contamination, and provides calibration only to one fixed type of sample. A far better way is a semiempirical approach based on standard point sources (section 6.2).

Each spectrometer must have a log book. All essential events, such as equipment fine-tuning or adjustment, must be documented. A maintenance program is intended for checking calibrations on a weekly or even on a daily basis. Energy and shape calibrations should be verified regularly, although they can be calculated from the data itself if required (Table 10). Checking of the efficiency calibration is of vital importance because there is no way to verify this from the data. A procedure should be established to count and analyze a mixture of sources in suitable intervals, such as $^{57}$Co (122 keV) and $^{60}$Co (1332 keV), for a short period, for example 10 min.

The laboratory must record the receipt of samples, the analysis process and the results. The analyst verifies that documented procedures have been followed. The essential information about the analysis must be documented in the laboratory notebook. The complete analysis process should be possible to check at any time. This goal is made easier to reach by software that saves the complete measurement and analysis configuration.

### 8.2 Technical Quality Requirements

Quality criteria and metrics play a key role for the quantitative evaluation of the measurement and analysis. Metrics should be applied to daily operations, performance evaluation on regular intervals and to software validation.

Evaluation metrics and their implementation are an important element of the quality assurance system. The definition of the metrics is followed by the development of implementation procedures and software for producing the reports required. The proposed criteria and procedures should not be too expensive, nor too difficult to achieve technically.

The following issues are of importance for the metrics development:

- requirements
- applicability of the metrics
- measurable and nonmeasurable aspects
- sources of data
- success criteria
- distribution of tasks
- frequency of evaluation and
- procedures for evaluation.

Control charts are perhaps the simplest technical quality elements. A control chart refers to a plot of the quantity involved as a function of time, including upper and lower warning and action limits (confidence limits are set often to 95% and 99.7%). This procedure is intended to monitor changes over time. Table 11 provides an example of subjects that could be evaluated regularly either through a control chart or using more advanced metrics.

### 8.3 Software Validation

The quality of software can be assessed through validation tests and developing evaluation metrics for the

---

**Table 10** An example of a quality assurance report generated during the analysis of a $\gamma$-spectrum. Energy and shape calibration were recalculated from the measured spectrum itself. The following peaks, which are present in the sample spectrum, were used to assure the energy calibration: 238.63 keV ($^{212}$Pb), 477.61 keV ($^7$Be), 583.19 keV ($^{208}$Tl), 860.56 keV ($^{212}$Pb), 1460.80 keV ($^{40}$K). The report shows that the original calibration data provided by the laboratory are out of range at large energies (cf. requirements in Table 11). The ratio $\text{fwtm/fwhm}$ tends to increase as a function of energy indicating charge collection problems at large energies; this deficiency is manifested as additional tails in the Gaussian peak (see Figure 6). In this case the original calibration data should not be used for the analysis and the software must have capability to cope with peak tails.

* Nuclide-ID percentage = 100% × (1 − missing nuclides/nuclides present).
operations. Validation tests are of particular importance in assessing the quality of the algorithms and the functional capability of the overall measurement and analysis system.

Software validation is a complex issue. Validation tests can be designed to focus on the performance of the individual components of the software, such as the peak search capability, or they could emphasize the overall analytical capability.

Some commercial programs have ISO 9000 certification. Many quality issues, such as documentation, are at high levels in these products. The certification, however, does not guarantee that the algorithms of the software are correct or are capable of performing the specific task of the laboratory at an adequate level. In fact, experience has shown that such software may indeed contain serious errors which are very difficult to correct because of certification or accreditation requirements.

Test spectra are necessary for software validation. These spectra should be accompanied by a certificate that specifies the nuclides, peak positions and peak areas (counts); the baseline should be realistic for the samples of interest. In general, there are no test spectra available that have universal acceptance by the users, software developers and regulatory bodies. It is not a simple task to prepare small peaks above certain continuum without violating statistics of the superimposed spectrum. The test spectra should be generated for the samples of interest, i.e. they should resemble routine spectra of the laboratory.

Test spectra can be generated by measurements or directly by software. An elegant possibility is to spike routine spectra with relevant radionuclides and then to test the performance of the software against this well-characterized nuclei composition. The statistical properties of the channel contents should be correct, and no model-dependent unrealistic features should be included.

The IAEA distributed in 1976 a set of nine artificial spectra. Another set of eight experimental spectra were generated for the IAEA software intercomparison in 1995. These spectra are now available from the IAEA. The International Electrotechnical Commission (IEC) has plans to produce test spectra, and some software vendors have their own test spectra but these are not generally available. Further international coordination and cooperation are necessary to provide test spectra for the quality assessment of software products.

Software for data processing is intended to detect large and small peaks, to identify the nuclides and to quantify the activities in a reliable manner. The metrics outlined in Table 11 suggests criteria for the technical performance of the automated operations and the interactive analysis.

The peak search capability should be sensitive and reliable. Only a few spurious peaks (type I error) should be identified, and real peaks should not be missed (type II error). The nuclide identification performance is another important performance indicator of the quality of the analysis. Here, in particular, the type I and type II error rates should be small. Type II error is more severe than type I error. In interactive analysis it is far simpler to remove peaks and nuclides than to locate and identify new peaks and nuclides.

8.4 Intercomparison and Performance Evaluation

The use of test samples and participation in intercomparison exercises give confidence in the overall analytical performance. The intention is to test the reliability and accuracy of the system rather than the performance of its individual components. Differences between laboratories may reveal systematic errors in the analytical capability, such as the omission of the true coincidence correction in the low-level counting in close geometries.

Performance evaluation of radionuclide measurement and analysis, either on a short-term or on a long-term basis, is an essential quality element. A systematic approach is necessary, but, above all, the quality culture of the laboratory is determined by the commitment of the staff to the goals, principles, and procedures defined by the management.

9 DISCUSSIONS

Determination techniques of radionuclides using $\gamma$-spectrometry have been developed to a high level since the early steps in the 1960s. The modern trends in $\gamma$-spectrometric measurements and analysis approach the level of complete automation. It will not take many years before the customers can buy a complete solution to the nondestructive determination of various nuclides, including calibrations, analysis and reliable quality assurance system.

Germanium can be purified to extremely low concentrations of impurity atoms. The continuous improvement of raw material makes it possible to produce larger and larger detectors. The trend toward higher counting efficiency will inevitably continue. The commercial availability of standard germanium detectors makes calibrations easy and reliable. The counting system can be applied to a new type of sample simply by calculating the new efficiency calibration curve without any measurement. The quality system is greatly simplified because calibrations and their documentation are eliminated, or at least partially eliminated. A large fraction of the quality issues is transferred from the users to the companies selling detectors, associated electronics and software.

Although germanium detectors dominate nuclide determination techniques, there is an incessant need to
develop a high-resolution detector (or at least an essentially better detector than NaI) that could be operated at room temperature. To reduce the leakage current, such a detector must have a band gap larger than 1 eV. The band gap should not, however, be too large, or the energy resolution would be deteriorated beyond the useful range. The charge carrier mobility should also be good and the charge collection efficient. High-\(Z\) materials, such as CdTe and \(\text{Hg I}_2\), are suitable for production of small detectors. The volumes range from 20 mm\(^3\) to a few cm\(^3\). Intensive research efforts aim to develop room temperature detectors with larger dimensions. Adding Zn seems to improve the quality of the detector. A comprehensive review on Cd\(_{1-x}\)Zn\(_x\)Te detectors is given by James et al.\(^{43}\)

The CdTe detectors have a better energy resolution than the NaI detectors, but their performance is by no means near the quality of a cooled germanium detector. Typical fwhm of the 57\(^\text{m}\)Cs peak (661.6 keV) is less than 2 keV for HPGe detector, 40–60 keV for the NaI detector and 15–25 keV for the CdTe detector. The resolution of the CdTe detector can be improved (<5 keV) through Peltier cooling (<0 °C). The peak-to-Compton ratio for CdTe and CdZnTe detectors is poor because of the small volume of the detector as the photons tend to escape the crystal.

Charge collection and long-term stability are severe problems of CdTe detectors.\(^{42}\) Owing to these difficulties, the pulse rise time varies more than in germanium detectors. Advanced digital signal processing mitigates this drawback, but despite all efforts the CdTe detectors are still individuals. The variation of the material is difficult to handle.

The room temperature detectors have many applications, such as uranium enrichment measurement (below 186 keV), spent fuel verification measurement (137\(^\text{Cs}, 661\) keV)\(^{42}\) and emergency preparedness monitoring (131\(^\text{I}, 364\) keV) in a nuclear power plant.

The demand of society for sensitive and reliable environmental monitoring requires low detection limits in assay systems. Indeed, the possibility to determine low amounts of radionuclides provides information on the releases of industrial operations, especially from the nuclear fuel cycle. Many applications, such as safeguards verification, benefit from the improved detection and identification capability. The nondestructive analysis has the inherent disadvantage that the measurement is performed together with the disturbing materials in the sample. The background nuclides within the sample are the dominating source of inaccuracy in many analyses. New methods have to be found to enrich nuclides of interest in the samples collected from the environment.

Air sampling and subsequent \(\gamma\)-spectrometric analysis of the filter are often the most sensitive methods for searching for nuclear signatures in the environment. The air sampler concentrates the airborne radionuclides to a small sample. The face velocity of the air through the filter is typically about 1 ms\(^{-1}\), whereas particles are deposited on surfaces with a velocity about three orders of magnitude smaller. The advantages of the enormous concentration capability cannot be fully utilized because of the similar enrichment of background nuclides, radon and thoron progenies in particular. This deterioration of the detection capability would be reduced if more advanced sampling methods were available. The man-made nuclides are often attached to larger particles than the background nuclides. It is possible to design equipment that would separate out the small background nuclides (<1 \(\mu\)m) from the main air stream. An impactor could sort the particles according to their size. However, the flow rate through such a device is small and thus the overall detection capability is not improved. A virtual impactor, i.e. a device that sorts particles according to their size without using impaction plates, would allow a much larger flow to pass through the system. Design of such an instrument for high-volume air sampling would improve the detection capability of man-made nuclides.

Particle fractionation provides ideal samples not only for \(\gamma\)-spectrometry but for other analyses as well, such as \(\alpha\)-spectrometry, without resorting to radiochemistry. In the future, the nuclide determination techniques are not only improved through counting and analysis equipment but also by adoption of advanced sampling systems.

\(\gamma\)-spectrum analysis has been, and it still is, a difficult task requiring human intervention. Recent development, based on a data-driven approach rather than on straightforward adoption of rigid algorithms, may ultimately provide complete explanation of a \(\gamma\)-spectrum, with every peak explained. An advanced expert system (section 6.6) can already perform automatically a better analysis than many analysts can do with traditional interactive software.

ACKNOWLEDGMENTS

We thank Dr Lars-Erik DeGeer and Dr Murray Matthews, Comprehensive Nuclear-Test-Ban Treaty Organisation, Vienna, and Mr Jarmo Ala-Heikkilä and Mr Timo Hakulinen, Helsinki University of Technology, for valuable comments on the manuscript. Mr Arto Leppänen and Mr Tapani Honkamaa, Radiation and Nuclear Safety Authority, Finland, have provided much of the data on the detector calibrations.

Inorganic mass spectrometric methods are powerful multielement analytical techniques for sensitive determination at the trace and ultratrace level, and for isotope ratio measurements in different materials (e.g. conducting, semiconducting and nonconducting solid samples; technical, environmental, biological, geological and water samples). An inorganic mass spectrometer consists of the following parts: the ion source for the evaporation, atomization and ionization of samples, the analyzer for the mass (and energy) separation of ion beams which are extracted from the ion source, and the ion detection system. The detection limits of solid-state mass spectrometric techniques by thermal ionization mass spectrometry (TIMS), glow discharge mass spectrometry (GDMS), laser ablation inductively coupled plasma mass spectrometry (LA/ICPMS) for the direct analysis of solid samples were determined down to the sub-nanogram per gram level. Resonance ionization mass spectrometry (RIMS) and accelerator mass spectrometry (AMS) are highly sensitive, selective ultrasensitive mass spectrometric techniques with detection limits up to $10^6$ atoms.

Inductively coupled plasma mass spectrometry (ICPMS) has been applied as the most important and sensitive mass spectrometric technique with its multielement capability for the determination of long-lived radionuclides in solid and aqueous samples, with detection limits the sub-picogram per liter. Isotope ratios can be determined by ICPMS using single ion collectors and multicollectors with a precision of 0.02% and 0.006% relative standard deviation (RSD) respectively. This review discusses the most important inorganic mass spectrometric techniques and their application for the quantitative determination of long-lived radionuclides in metals, alloys, and nonconductors, as well as in environmental, biological and geological samples, and radioactive waste materials. The application of these methods to isotope ratio measurements is also discussed.

1 INTRODUCTION

Inorganic mass spectrometric methods, with their ability to provide a very sensitive multielement determination of trace and ultratrace elements and precise isotopic analysis, have been increasingly established for the determination of long-lived radionuclides especially in environmental materials such as waters, and geological and biological samples nuclear materials and radioactive waste, high-purity materials, and ceramics and glass. Such mass spectrometric measurements of long-lived radionuclides are of additional interest in areas such as radiobioassay, environmental monitoring, decontamination and environmental remediation, health, safety, nuclear waste characterization (radioactive waste control) and management of radioactive waste for storage and disposal. The applications fields of inorganic mass spectrometry as a universal and extremely sensitive analytical method for the simultaneous determination of long-lived radionuclides in the trace and ultratrace range, and their isotope ratio measurements are already very wide and will increase as the sensitivity and precision improve and ever-decreasing detection limits are possible. The important applications of long-lived radionuclides in analytical chemistry are summarized in Table 1. The determination of the concentration and precise isotopic analysis of radioactive elements (e.g. the terrestrial sources of radioactivity, $^{238}$U, $^{235}$U, $^{232}$Th and their decay nuclides) by inorganic mass spectrometry is used for environmental research, in solid-state research and for controlling the purity of, for example, high-purity metals, alloys, semiconductors and insulators for microelectronics. Furthermore, the measurement of contamination and enrichment of selected radionuclides (e.g. $^{129}$I as an environmental indicator of nuclear accidents, $^{99m}$Tc or $^{79}$Se as fissions products, and $^{237}$Np, $^{239}$Pu, $^{241}$Pu, $^{241}$Am) at ultralow levels during the environmental monitoring required as a result of...
fallout from nuclear weapons testing, the operation of nuclear power plants or after nuclear accidents are of increasing interest. Long-lived radionuclides have also been used for tracer experiments in biological and geological research, and the application of isotopic dilution methods using long-lived radioactive isotopes. On the other hand, the determination of long-lived radionuclides by the isotope dilution procedure can be carried out with the application of stable, enriched isotopes.

Among the existing analytical physical methods (such as optical emission spectrometry, atomic absorption spectrometry, radioanalytical techniques, neutron activation analysis, and X-ray spectrometry) inorganic mass spectrometry is preferred for the determination of very low concentrations of radionuclides and their isotope ratios at the ultratrace level. Inorganic mass spectrometry has been developed into a congruent method of the well-established classical radioanalytical techniques because of easier sample preparation steps and excellent detection capability, especially for the characterization of radionuclides with half-lives >10^4 years in environmental samples and waste materials with very low radioactivity.

The development of analytical methods for the determination of long-lived radionuclides at ultratrace concentration levels in environmental samples and radioactive waste materials from nuclear reactors has focused on improving microanalytical techniques in order to reduce the sample volume, to improve the precision (RSD) of measurements and the detection limits. For example, quality control of radioactive waste packages requires powerful and fast analytical methods which allow many samples to be measured in a short time, with a high degree of accuracy and precision. Using conventional radiochemical methods for the determination of long-lived radionuclides at low concentrations, a careful chemical separation of the analyte, e.g. by extraction or chromatography, is often necessary. Such complete separation steps of the interferents and enrichment of long-lived radionuclides in order to achieve low detection limits are generally time-consuming.

This review discusses the most important mass spectrometric techniques and their application for quantitative determination and isotope ratio measurements of long-lived radionuclides.

2 APPLICATION OF DIFFERENT MASS SPECTROMETRIC TECHNIQUES FOR DETERMINATION OF RADIONUCLIDES

2.1 Methods of Solid-state Mass Spectrometry

In trace element determination and isotope analysis of long-lived radionuclides in solids, very sensitive multielement solid state mass spectrometric methods allow a direct analysis of the sample material without any chemical sample preparation. The mass spectrometric analytical techniques with multielemental capability used for the determination of radionuclides are LA/ICPMS, GDMS, and secondary ion mass spectrometry (SIMS), TIMS, AMS and RIMS have been used for sensitive ultratrace analysis and precise determination of isotopic ratios of selected long-lived radionuclides in solid samples. Because the mass spectrometric technique is determined by the evaporation of solid sample (e.g. thermal evaporation, laser ablation, evaporation and atomization of sample in plasmas, or using electron beam or ion bombardment) and ionization method applied (e.g. electron impact ionization, multiphoton ionization using a laser beam and ionization...
during the sputtering process) the ion separation system to be used is essentially defined by the physical properties of the ions formed (e.g. initial energy) and the ionization itself (e.g. formation of disturbing molecular and cluster ions, often with great intensity). Both static magnetic sector fields (single-focusing) or combinations of electric and magnetic sector fields (double-focusing) are used for ion separation as well as dynamic ion separation systems (e.g. quadrupole mass spectrometer, time-of-flight (TOF) mass spectrometer, Fourier transform mass spectrometer and ion trap mass spectrometer). Ion detection can be performed electrically (with photomultiplier, channel plates, Channeltron or Faraday cup).

The main advantage of solid state mass spectrometry is that a possible danger of contamination during sample preparation and the occurrence of numerous interferences in the mass spectra of aqueous solutions after digestion of sample with acids (in comparison to ICPMS) can thus be reduced to a minimum. However, quantification in solid state mass spectrometry generally proves difficult if no suitable standard reference materials are available.

2.1.1 Thermal Ionization Mass Spectrometry

TIMS is a well recognized analytical technique for the precise and accurate measurement of isotopic ratios for different elements with a precision of better than 0.01%. In TIMS a small volume (1–10 µL) of aqueous sample solution, which contains some ng to µg of the analyte to be analyzed, is deposited on a cleaned filament surface (e.g. high-purity Re) and evaporated to dryness. The most frequently applied technique in TIMS works with two filaments which are arranged opposite each another. One of the filaments is used for the evaporation of sample by thermal heating and the other for ionization of evaporated atoms and molecules on the hot filament surface. Ions formed by thermal ionization possess low initial energies (0.1–0.2 eV), therefore, generally, single magnetic sector field mass spectrometers were used for ion separation. At present, two magnetic sector field instruments (e.g. MAT 262, Finnigan MAT, Germany or Sector 54 from Micromass, UK) are commercially available on the analytical market. Instruments with a multiple collector are important for precise and accurate measurement of isotopic ratios in TIMS. A fundamental paper on fractionation correction in TIMS is that by Habfast. Different effects could be considered by different internal calibration or by using isotopic standards (e.g. from the National Institute of Standards and Technology (NIST), Gaithersburg, USA; or Institute of Reference Materials and Measurements (IRMM), Geel, Belgium) with well-known isotopic ratios of an element of interest.

The capability of TIMS in precise isotopic ratio measurements, as the major application field of this analytical technique, is used in accurate trace element determination of radiogenic elements for determining element concentration by the isotope dilution method using high-enriched isotopic spikes. Interesting investigations of TIMS and IDA were performed in Heumann’s group by the determination of U and Th (and other elements) in, e.g. high-purity aluminum and refractory metals and silicides of Mo, W and Ta and silicon oxide after trace–matrix separation. Impurities of the radioactive elements U and Th and their decay products at the picogram per gram level in high-purity refractory metals and their silicides, which have been increasingly used for gate electrodes, interconnections and diffusion barriers in integrated circuits, affect the performance of integrated circuits. An excellent review of the isotope dilution technique using TIMS, including applications for geological dating and for the determination of long-lived radionuclides is given by Heumann.

TIMS has been extensively used by Aggarwal and Crain for the accurate determination of half-life of a number of transactinium isotopes (e.g. 241Pu, 242Pu, 243Am, 242Cm) and of the fission yield of stable and long-lived fission products in thermal neutron induced fission of 233U, 239Pu and 241Pu.

The application of mass spectrometry in the determination of U and Th in high-purity metals and alloys is summarized in Table 2.

TIMS requires an often time-consuming sample preparation (digestion of solid samples and trace–matrix separation) and therefore has been replaced by the more sensitive ICPMS in the past few years.

2.1.2 Glow Discharge Mass Spectrometry

GDMS was established as a powerful and efficient analytical method for the direct trace element and depth profile analysis of solids. This mass spectrometric technique uses an argon gas glow discharge at a pressure of 0.1–10 torr as an ion source. The cathode surface consisting of the sample material is sputtered by Ar ions which are formed in a low-pressure plasma and accelerated towards the cathode. Sputtered neutral particles are ionized in the glow discharge plasma (“negative glow”) by Penning and/or electron impact ionization and charge exchange processes. For the direct analysis of solid samples the commercial direct current glow discharge

mass spectrometer VG-9000 (VG-Elemental, Thermo Instruments, UK), a double-focusing sector field mass spectrometer with Nier–Johnson geometry, is available for the determination of trace elements in electrically conducting materials with detection limits in the nanogram per gram concentration range and lower with reproducibility of about ±10%. The analysis of nonconducting materials by dc GDMS is difficult due to charge-up effects on the sample surface. Different techniques such as mixing nonconducting powdered samples with a high-purity metal powder (or high-purity graphite) or the use of a secondary cathode have therefore been applied for the analysis of electrically insulating samples by dc GDMS. Betti⁴¹ used the VG 9000 for different applications to characterize radioactive waste materials in electrically conducting and nonconducting materials, e.g. for different types of nuclear fuels, alloys containing Pu and U, cladding materials, nuclear waste glasses.

2.1.3 Laser Ablation Inductively Coupled Plasma Mass Spectrometry

To an increasing extent LA/ICPMS is the method of choice for the direct analysis of solid samples. This analytical technique uses the evaporation of sample material by a focused or defocused laser beam, mostly using neodymium yttrium aluminum garnet (Nd:YAG) lasers with λ = 1064 nm and λ/2 = 532 nm or λ/4 = 266 nm, in an inert gas atmosphere (e.g. Ar) under normal pressure and post-ionization of evaporated and ablated material in an inductively coupled plasma of the ion source of an ICPMS. Most commercial laser ablation systems (e.g. LSX-200, CETAC, USA and LUV 266, Merchantek, USA) are coupled to low-resolution quadrupole analyzers. In our laboratory a noncommercial laser ablation system was coupled to a quadrupole-based ICPMS (“ELAN 6000”, Perkin Elmer SCIEX, Canada) and double-focusing sector field mass spectrometer (“ELEMENT”, Finnigan MAT, Germany) for the characterization of solid radioactive waste materials.⁴⁸ The experimental arrangement of LA/ICPMS is shown in Figure 1. For the determination of long-lived radionuclides in nonconducting materials, a synthetic laboratory standard with a concrete matrix was doped with a low concentration of long-lived radionuclides (e.g. ⁹⁹Tc, ¹²⁴I, ²³²Th, ²³³U, ²³⁷Np, ²³⁸U). Figure 2 shows a part of mass spectrum of long-lived radionuclides in concrete measured by LA/ICPMS. The detection limits determined for Tc, U and Np in a blank concrete sample were in the low pg g⁻¹ range. The detection limits are lower by more than one order of magnitude using double-focusing sector field ICPMS in comparison to quadrupole LA/ICPMS.

Table 3 summarizes some selected applications of mass spectrometry in the trace and ultratrace analysis of long-lived radionuclides in nonconductors and solid radioactive waste.

2.1.4 Resonance Ionization Mass Spectrometry

In RIMS one or more lasers are tuned precisely to the wavelength required for the excited states and ionization of evaporated atoms in order to obtain a highly selective ionization of analyte. For the formation of a neutral gas by evaporation of solid or liquid samples all well-known sources of evaporation (e.g. thermal vaporization on a hot Re filament, laser and spark ablation, glow discharge, ion bombardment, evaporation using electron beam) were applied.
RIMS is a highly selective and sensitive method for trace analysis of radiotoxic elements in environmental, biological and technical samples. The determination of Pu after electrolytic separation from soil, air filters or urine was described by Erdmann et al.\textsuperscript{(51)} with detection limits of $10^6$–$10^7$ atoms. Nunnemann et al.\textsuperscript{(13)} determined Pu isotope ratios in environmental samples in order to distinguish between Pu from nuclear power plants and from nuclear fallout after nuclear weapons tests. The possibility of determining $^{89}$Sr and $^{90}$Sr at the ultratrace level in environmental samples by using RIMS has been reported by Wendt et al.\textsuperscript{(38)}

2.1.5 Accelerator Mass Spectrometry

AMS is a highly selective (and extremely expensive) ultrasensitive mass spectrometric technique. The sensitive determination of exotic radionuclides such as $^{14}$C, $^3$He, $^{10}$Be, $^{26}$Al, $^{32}$Si, $^{129}$I or $^{205}$Pb is carried out by ion sputtering (e.g. using a Cs\textsuperscript{+} primary ion source). The sputtered secondary analyte ions were extracted into a two-stage mass filter. The mass-separated ions were accelerated in a tandem accelerator to energies of some MeV and were stripped in a following gas target or foil stripper in order to separate isobaric atomic and molecular ions. After the deceleration of ions and a final mass separation the ions were sensitively detected.

Recently, AMS was able to determine $^{236}$U/$^{238}$U isotope ratios in the range $10^{-9}$–$10^{-14}$ for evidence of $^{235}$U in environmental samples.\textsuperscript{(52)} With AMS absolute detection limits of $10^6$ atoms are reached for isotopes such as $^{239}$Pu.\textsuperscript{(53)}

With its capability of providing isotopic abundance ratios as low as $10^{-15}$ for very small samples, AMS was developed for the detection of extremely low concentrations of long-lived radionuclides for research in geochronology and archaeology.

2.2 Inductively Coupled Plasma Mass Spectrometry

As the most popular analytical technique for fast multielement determination of elements in the trace and ultratrace concentration range in aqueous solutions\textsuperscript{(54,55)} ICPMS has been increasingly used for the determination...

DIHEN, direct injection high-efficiency nebulizer; DF/ICPMS, double-focusing inductively coupled plasma mass spectrometry.
of long-lived radionuclides with very low activity. In contrast to solid-state mass spectrometry, ICPMS is being used for the characterization of long-lived radionuclides in aqueous and solid samples after sample dissolution owing to the simple quantification procedure of the aqueous solution. The principle of ICPMS can be described as follows. The chemical compounds contained in the sample solution are decomposed into their atomic constituents in an inductively coupled argon plasma and ionized at a high degree of ionization (>90% for most chemical elements) with a low fraction of multiply charged ions (≈1%). The positively charged ions are extracted from the inductively coupled plasma (at atmospheric pressure) into the high vacuum of the mass spectrometer via an interface.

At present different commercial double-focusing sector field ICPMS, e.g. “ELEMENT” (Finnigan MAT, Bremen, Germany), “PlasmaTrace 2” (Micromass Ltd, UK), “AXIOM” (VG Elemental, UK) and “JMS-Plasma X2” (Joel, Japan), and quadrupole-based ICP mass spectrometers (e.g. Perkin Elmer Sciex, Hewlett Packard, VG Elemental, Varian GmbH analytical instruments, Spectro Analytical Instruments, Micromass) are available on the international market. In the low-resolution mode, the element sensitivity of commercial double-focusing sector field ICPMS is significantly higher than conventional quadrupole ICPMS. The extreme element sensitivity of double-focusing sector field ICPMS permits ultratrace analysis down to the sub-fg mL⁻¹ concentration range. In Table 4 the detection limits for double-focusing ICPMS “ELEMENT” with plasma-shielded torch and “PlasmaTrace” with ultrasonic nebulizer are compared. A calibration graph for ²⁴¹Am to determine the detection limit using the ICPMS “ELEMENT” with a plasma-shielded torch is shown in Figure 3. For the determination of long-lived radionuclides the multielement capability is used as a main advantage of powerful ICPMS, which means the actinides are determined quasi-simultaneously by ICPMS. In contrast, if isobaric interferences of long-lived radionuclides with stable isotopes of impurities are expected, a matrix separation and/or an enrichment of long-lived radionuclides is required.

Yamamoto et al. (56) determined ⁹⁹Tc in environmental and radioactive waste samples, where there was the possibility of isobaric interference by ⁹⁹Ru⁺ (and ⁹⁸MoH⁺) ions. These authors suggested avoiding such interference by separating ⁹⁹Tc using different solvent extraction and purification techniques with anion exchange after leaching of geological samples. They determined ⁹⁹Tc with an absolute detection limit of 0.25 pg, corresponding to 0.16 mBq, using a double-focusing sector field ICPMS (PlasmaTrace, VG Elemental Ltd.) and analyzed sediment samples from the Irish Sea.

Eroglu and associates (10) investigated the enrichment and separation of ⁹⁹Tc from seawater by anion exchange and determined a detection limit (for a 14-mL sample volume) of 0.03 ng L⁻¹ using a quadrupole-based ICPMS (HP 4500, Hewlett-Packard).

The application of mass spectrometry in trace, ultratrace and isotope analysis of long-lived radionuclides in biological, geological and environmental samples (57–60) is summarized in Table 5.

2.2.1 Solution Introduction in Inductively Coupled Plasma Mass Spectrometry Using Micronebulizers

The development of microanalytical methods for the precise determination of nuclide abundances and concentration of long-lived radionuclides at ultratrace concentration levels in radioactive wastes and also for controlling contamination from radioactive waste in the environment is a challenging task. In order to analyze small sample volumes, micronebulizers (MCN-100, Cetac Technologies, USA and MicroMist, Glass Expansion, Australia)$^{(61)}$ and the DIHEN (J.E. Meinhard Associates, USA)$^{(20)}$ have been increasingly used instead of high solution volume consuming ultrasonic nebulizers for determining long-lived radionuclides by the solution introduction into the inductively coupled plasma of an ICPMS. Owing to direct nebulization of the sample solution in the inductively coupled plasma with the DIHEN (with an analyte transport efficiency into the plasma of 100%), and the reduction of the solution uptake rate and the sample size to the 1 µL min$^{-1}$ and fg range, respectively, very sensitive measurements of long-lived radionuclides in aqueous solutions are possible.$^{(20)}$ Whereas with a quadrupole-based ICPMS using a micronebulizer the detection limits of long-lived radionuclides ($^{230}$Th, $^{235}$U, $^{238}$U, $^{239}$Pu and $^{241}$Am) in aqueous solutions varied from 0.012 to 0.11 ng L$^{-1}$ in double-focusing sector field ICPMS with a shielded torch the detection limits are determined to be 0.0003–0.0008 ng L$^{-1}$. $^{(4)}$

The determination of $^{99}$Tc in a highly radioactive evaporator concentrate from a nuclear power plant$^{(62)}$ was performed after complex chemical sample preparation by DF/ICPMS with a shielded torch using the microconcentric MicroMist nebulizer with minicyclonic spray chamber. The detection limit with double-focusing ICPMS was determined as 5 pg L$^{-1}$, corresponding to an activity of 3 µBq mL$^{-1}$, in comparative measurements by quadrupole-based ICPMS (ELAN 6000, Perkin Elmer Sciex) the detection limit of $^{99}$Tc was 0.1 ng L$^{-1}$. $^{(4)}$
2.2.2 Ultratrace Analysis of Radionuclides in Small Sample Volumes

The application of flow injection is useful for sample introduction to measure small sample volumes of radioactive waste solutions in order to minimize radioactive contamination in the ICPMS.44,63 Figure 4 shows the principle of flow injection for solution introduction of small sample volumes. To handle microliter amounts of an aqueous solution of long-lived radionuclides a commercial high-performance liquid chromatography (HPLC) injection valve was coupled to a micronebulizer for small droplet formation and a minicyclonic spray chamber. The small sample volume (sample loop: >1 μL) of standard or radioactive waste solution is introduced by this HPLC injection valve into a continuous flow of 2% nitric acid. For example, a 237Np standard solution (sample loop: 20 μL; Np concentration: 10 ng L−1 and 100 ng L−1) was measured with a precision of 2.0% and 1.6% (RSD, n = 5), respectively.44 The transient signals of 241Am+ and 237Np+ for 10 ng L−1 and 100 ng L−1 measured by DF/ICPMS with plasma-shielded torch are shown in Figure 5. Furthermore, the flow injection method was applied in our laboratory for isotope dilution analysis of Th in ICPMS. In this experiment a 2 μL L−1 232Th solution (continuous flow) was spiked with 20 μL of 5 μg L−1 highly enriched 230Th (99.85%) for quantiative Th determination in radioactive solutions.61

2.2.3 Application of Flow Injection Technique, High-performance Liquid Chromatography and Capillary Electrophoresis for Coupling to Inductively Coupled Plasma Mass Spectrometry

The most important problem in determining long-lived radionuclides in radioactive waste or environmental samples is the appearance of isobars of radioactive and stable nuclides of the same mass but different atomic number, thus causing interference in the mass spectra. In order to separate isobars, such as long-lived 173Lu from stable 173Yb, on-line HPLC (for chromatographic separation of a lanthanide mixture into the individual elements) coupled to an ICPMS (for the mass spectrometric determination of the nuclides from each of the previously separated elements as a function of their mass) is the method of choice. In past years on-line ion chromatography ICPMS has been increasingly used for the characterization of radioactive materials and environmental samples using quadrupole-based ICPMS.50,64,65 The use of ion chromatography for the determination of fission products and actinides in nuclear applications is reviewed by Betti.17 On-line trace enrichment by flow injection using a microcolumn of activated alumina and mass spectrometric determination of uranium in mineral, river and seawater has been described by Dadfarnia and McLeod.16

Flow injection with on-line preconcentration using solid-phase adsorption on a mini-column of 99Tc, 230Th and 234U at ultratrace levels in soils is described by Hollenbach et al.67 Detection limits in the soil for 99Tc, 230Th and 234U were 11 mBq g−1 (0.02 ng g−1), 3.7 mBq g−1 (0.005 ng g−1) and 0.74 mBq g−1 (0.003 ng g−1) respectively.

An analytical procedure has been developed for the determination of spallation nuclides in an irradiated (with 800 MeV protons) Ta target of a spallation neutron source...
using HPLC coupled on-line to ICPMS.\textsuperscript{(58,68)} Owing to expected isobaric interferences from long-lived radionuclides and stable isotopes in the irradiated Ta target, HPLC was useful for the chemical separation of analytes before the mass spectrometric measurements. The determination of spallation nuclides in irradiated Ta was performed by HPLC coupling on-line with double-focusing sector field ICPMS after dissolution of Ta in an HNO\textsubscript{3}/HF mixture and matrix separation by liquid–liquid extraction of the Ta matrix (in order to reduce the high \textsuperscript{182}Ta activity). The theoretical results of spallation yields of Ta are verified by measurements of the concentration of spallation nuclides of irradiated Ta.\textsuperscript{(68,69)} A further reduction of the sample volume from 100 µL using HPLC/ICPMS in the nL range is interesting for the characterization of high-radioactive solution. Therefore, the on-line coupling of capillary electrophoresis with ICPMS was proposed in our laboratory in order to separate spallation lanthanides in radioactive solutions.\textsuperscript{(70)} Figure 6 shows the ICP mass spectrum of spallation nuclides in the mass range of lanthanides in the irradiated Ta target (a) before lanthanide separation and by on-line CE/ICPMS on about 30 nL sample volume; (b) with lanthanide separation in the mass range from Pm to Lu using the double-focusing sector field ICPMS.

2.2.4 Precise Measurements of Isotope Ratios by Inductively Coupled Plasma Mass Spectrometry

Isotope ratio measurements of radiogenic elements are of great importance in the nuclear industry, where TIMS has occupied a favored position in the last few decades for routine measurements (e.g. quality assurance of fuel material; isotopic composition of U and Pu; reprocessing plant, nuclear material accounting and radioactive waste control).
For example, Callis and Abernathey[34] developed a rapid high-precision analytical technique for the determination of isotope ratios of U and Pu by total sample volatilization using multiple-filament TIMS with a commercial multicollector instrument (VG-354, VG Isotopes). Run-to-run reproducibilities of <0.02% RSD have been obtained for isotope ratios of U and Pu. Inkret et al.[73] reported on applications of TIMS to the sensitive detection of 239Pu and 240Pu intakes. The determination of Pu concentration in urine samples yielded an average measurement uncertainty of 3.8 µBq per 24 h, a 40-fold improvement over the measurement uncertainties associated with radiochemistry/o-spectroscopy analytical methods.

The application of laser ablation multicollector ICPMS for in situ U and Th isotopic analysis to certified glass standards and naturally occurring opal is described by Stirling et al.[74]

At present TIMS is being increasingly replaced for precise isotope ratio measurements by ICPMS due to its excellent sensitivity and good RSD. For example, Agarande and colleagues investigated the long-term stability of low concentration U reference solutions by using ICPMS.[75] The excellent precision of isotope ratio measurements of long-lived radionuclides by ICPQMS and double-focusing sector field ICPMS has been demonstrated in different studies from our laboratory.[4,8,20,61,71,77] Selected applications of mass spectrometry for the determination of isotope ratios are summarized in Table 6.

3 CONCLUSIONS

In addition to solid-state mass spectrometric techniques, which allow the direct determination of long-lived
radionuclides in the picogram per gram range with a minimum of sample preparation, ICPMS, especially with on-line coupling techniques (ETV, HPLC, ion chromatography, flow injection) with detection limits in the femtogram per milliliter range is an excellent tool for the analysis of aqueous solutions. Numerous, quite different applications demonstrate the excellent capability of inorganic mass spectrometry for determining very low activity radionuclides, due to their low detection limits for the evidence of contamination from radioactive waste in the environment (in biological and medical samples, waters or geological materials).

The significance of ICPMS in precise isotope ratio measurements at ultratrace levels is increasing, especially when multicollector, and/or double-focusing sector field instruments are used.

37. M. Nunnemann, N. Erdmann, H.-U. Hasse, G. Huber, J.V. Kratz, P. Kunz, A. Mansel, G. Passler, O. Stetzer,

This article describes the use of neutron activation analysis (NAA) for the quantitative determination of very long-lived radionuclides in the environment and nuclear waste. NAA is mainly known as a reliable trace element analysis method for different kinds of samples, but because of its sensitivity and isotope specificity it has also found applications in the determination of a few radionuclides with half-lives of the order of $10^4$ years or longer, namely $^{99}$Tc, $^{129}$I, $^{135}$Cs and $^{237}$Np.

NAA can be dated to the time of Hevesy and Levi (1936) who published their first paper of the method in 1936. Following the development of nuclear reactors in the early 1950s, the possibilities of applying NAA to trace element analysis were recognized. The invention of high-resolution Ge(Li) detectors in the 1960s and more recent advances in computers and automation during the 1970s and 1980s have made possible application of NAA to research studies involving large numbers of samples.

However, the need for a research reactor for irradiation and the advances in new types of mass spectrometers have decreased the use of NAA in the 1990s. When a research reactor is available, NAA still has some use for the determination of a few long-lived radionuclides, for the following reasons. The detection limits for some nuclides are lower than those obtainable with most kinds of mass spectrometry. The method has a substantial freedom from systematic errors. The physical processes are well understood. High-resolution $\gamma$-ray spectroscopy allows the qualitative identification of the nuclides present, and also their quantitative determination. The density of $\gamma$-lines is small, allowing their separation, and the energy is high, rendering matrix errors small. The method is complementary to other methods commonly in use, which are therefore likely to give a different bias in the result. The method is not sensitive to contamination, because short-lived nuclides are measured.

2 PRINCIPLES OF NEUTRON ACTIVATION ANALYSIS

The sample to be analyzed is irradiated with neutrons in a nuclear research reactor. The nuclides in the sample undergo nuclear reactions in which the nucleus absorbs a neutron and practically simultaneously some excitation...
energy in the form of $\gamma$-radiation is emitted. This is called an $(n,\gamma)$-reaction. Other reactions also occur but they are of lesser significance in NAA. The product nuclide may be either radioactive or stable. The activity of a produced radionuclide is given by Equation (1):

$$A = N[\epsilon_{\text{th}} + \epsilon_{\text{epi}}] \left(1 - e^{-\frac{\ln 2 t_i}{T}}\right) e^{-\frac{\ln 2 t_i}{T}}$$

where $A$ = activity in disintegrations per second (Bq), $N$ = number of target atoms, $\epsilon_{\text{th}}$ = thermal neutron flux, $\epsilon_{\text{epi}}$ = epithermal neutron flux, $\epsilon_{\text{th}}$ = average thermal neutron cross-section, $I$ = effective resonance integral or epithermal cross-section, $T$ = half-life of product radionuclide, $t_i$ = irradiation time and $t_d$ = decay time between the end of irradiation and middle of measurement. The half-life and the irradiation and decay times have to be expressed in the same units. The neutron flux in the equation is expressed as the number of neutrons per square centimeter per second. The cross-section is expressed in square centimeters; in tabulations it is expresses in barns (1 barn = $10^{-24}$ cm$^2$).

New radionuclides with half-lives ranging from seconds to years are produced in these reactions. The activity of the radionuclide produced is measured using high-resolution $\gamma$-spectrometry, as described in the article $\gamma$-Spectrometry, High-resolution, for Radionuclide Determination. The amount of the original radionuclide (number of nuclides, $N$) can be calculated from Equation (1) when the physical parameters and the detector efficiency as a function of $\gamma$-ray energy are known. It can also be calculated from Equation (2) when a standard with a known concentration of the same radionuclide is irradiated together with the sample and measured under the same conditions as the sample:

$$N_i = \frac{N_0 A_0 e^{-\frac{\ln 2 t}{T}}}{A_{st}}$$

where $i$ is the time elapsed between the measurements of the standard and the sample.

## 3 NEUTRON ACTIVATION ANALYSIS OF RADIONUCLIDES

### 3.1 General

The benefit of NAA compared with direct radiometric measurement of the parent nuclide is based on the following. For some radionuclides the analytical characteristics can be improved by neutron activation, which produces radionuclides with shorter half-lives than those of the parent nuclides. These have higher specific activities than the parent nuclide, and if the reaction cross-section and other nuclear characteristics are favorable a considerable improvement can be obtained. An especially significant improvement is obtained when a $\gamma$-emitting nuclide is produced from a nuclide which only emits $\beta$-particles. The reason for this is that the measurement of $\gamma$-radiation is more specific than the measurement of $\beta$-radiation, which does not have a discrete energy.

There are a few long-lived radionuclides which need to be determined because they are produced in nuclear fuel, and may pose a hazard in the final disposal of nuclear waste. Neutron activation produces nuclides with shorter half-lives from some of these radionuclides. Table 1 shows the reactions and the improvement in the specific activities when the sample is irradiated for 15 h in a neutron flux of $10^{13}$ nc m$^{-2}$ s$^{-1}$.

### Table 1 Improvement of specific activity by neutron activation

Of these possible applications, only the determination of $^{99m}$Tc, $^{129}$I, $^{135}$Cs and $^{237}$Np has been reported and only the determination of $^{129}$I and $^{237}$Np has been of substantial significance in research.

### 3.2 Technetium-99

Theoretically, NAA is more sensitive than $\beta$-counting for the determination of $^{99}$Tc, although in practical work poorer detection limits are observed. The detection limit is not low enough for the analysis of environmental samples, but because NAA has the advantage over $\beta$-counting of being specific, it is used for the analysis of nuclear waste.

The NAA of $^{99}$Tc can be based on two reactions, $^{99}$Tc($n,\gamma$)$^{100}$Tc and $^{99}$Tc($n,n'$)$^{99m}$Tc. Another method of producing $^{99m}$Tc is by the $(\gamma,\gamma')$ reaction. The half-life of $^{100}$Tc is 15.5 s and it emits $\gamma$-rays of 540 and 591 keV with low intensity (7 and 6%, respectively). $^{99m}$Tc, on the other hand, has a half-life of 6 h and emits a $\gamma$-ray of 140 keV with an intensity 87%. When counting $^{100}$Tc, which has a very short half-life, $^{99}$Tc has to be separated from the sample prior to irradiation.

For NAA a preirradiation separation procedure may be used. Here the procedure of Bate(3) is described briefly.
99mTc or 95mTc is added as tracer for yield determination. Technetium is extracted into cyclohexanone and then back-extracted into water by diluting the cyclohexanone with water and carbon tetrachloride. The water solution is made basic and the Tc is adsorbed on Bio-Rad 1-X1 ion-exchange resin in a small column suitable for neutron irradiation. The resin is irradiated for 11 s and counted for 30 s.

When 99mTc is counted, the sample can be directly irradiated and followed by a radiochemical separation. No papers on the analysis of real samples using this method have been published.

### 3.3 Iodine-129

NAA is a significantly more sensitive method than particle counting for the determination of 129I. It has been stated that NAA is 10^6 times more sensitive than β-counting. The best published detection limit is 0.15 × 10^-4 mBq. As a consequence, NAA seems to be the most commonly used method for the analysis of 129I as indicated by the large number of publications on the subject.

The analysis is based on the reaction 129I(n,γ)130I. The half-life of 130I is 12.4 h. The main γ-ray is of 536 keV to the extent of 99%. Other prominent lines are 418, 668 and 734 keV. Because of the extremely low concentrations of 129I in environmental samples, the production of 129I through reactions other than (n,γ) is a potential source of error. The production of 129I via the threefold reaction 127I(n,γ)128I(n,γ)129I(n,γ)130I is a potential source of error. The effect of this error has to be controlled and therefore the 129I/127I ratio always has to be determined. This can be done by determining 127I through the 127I(n,γ)128I reaction. The half-life of 128I is 25 min. A more convenient method is to use the reaction 127I(n,2n)126I because the half-life of 126I is 13 days and it can be measured simultaneously with 130I. This is possible when the fast flux density is sufficiently high. Other reactions producing 130I activity also occur. To avoid these errors, 130I (or I) has to be separated from Cs, U and Te prior to the irradiation. Br is especially troublesome owing to the similarity of its chemical properties.

Because of the sources of error described above, a radiochemical separation is almost always required for the NAA determination of 129I, regardless of the sample type. The lower the concentrations, the more elaborate are the separations needed. The separation can be divided into three parts: (1) extraction of 129I from the sample, (2) preirradiation purification and (3) postirradiation purification before counting. When a moderate detection limit is required, step 3 may be omitted.

Soil and vegetation samples may be directly heated in a stream of oxygen in a quartz tube. The evaporated iodine is either adsorbed on activated charcoal or in a solution of KOH and K2SO3. Iodine can also be distilled from a solution as elemental iodine. Ion exchange can also be used as a step in the separation of iodine. The yield is determined either by adding stable I carrier or 125I tracer. The distillation or combustion step is usually followed by the classical extraction cycle based on oxidation/reduction using CCl4 as an organic solvent. One novel method is to separate I from Br in the gas phase using a hydrated manganese dioxide (HMD) column. The final sample for irradiation can be prepared by evaporation of the sample on to a foil, adsorption on an ion-exchange resin or activated charcoal or by evaporation of elemental iodine into a quartz ampule.

Stable iodine is usually added as a carrier for post-irradiation separation. Again the most commonly used method is the oxidation/reduction extraction cycle with carbon tetrachloride. Other methods are combustion followed by HMD separation and adsorption on activated charcoal. Usually a combination of two of these is employed. Finally, the sample is prepared for counting by AgI or PdI2 precipitation. Sometimes the sample is absorbed on activated charcoal for counting or the sample is counted in liquid form.

### 3.4 Cesium-135

135Cs is a β-emitter with a specific activity of 43 mBq ng⁻¹. Therefore, its determination by radiometric means is very difficult. Very few references on the determination of 135Cs can be found in the literature. Stamm determined 135Cs by NAA in sodium coolant. The determination was based on the 135Cs(n,γ)136Cs reaction with a thermal cross-section of 8.7 barn and a resonance integral of 66 barn. 136Cs has a half-life of 13.7 days and emits several γ-rays, the most important of which are 341, 818 and 1048 keV with respective absolute intensities of 49, 100 and 80%. No details of detection limits were given.

### 3.5 Neptunium-237

237Np has a specific activity of 26 mBq ng⁻¹. The extremely low concentrations found in nature may be determined by NAA after extensive chemical separations prior to measurement. With a sample of 100 g, the detection limit for NAA is 0.2 mBq kg⁻¹, which means a detection limit of 0.02 mBq per sample.

NAA of 237Np is based on the reaction 237Np(n,γ)238Np. The product nuclide has a half-life of 2.12 days and γ-energies 924 keV (3%), 984 keV (24%), 1026 keV (8%) and 1029 keV (17%). Uranium may interfere
with the analysis by producing $^{237}$Np via the reactions $^{238}$U(n,2n)$^{237}$U$^{237}$Np and $^{235}$U(n,γ)$^{238}$U(n,γ)$^{237}$U$^{237}$Np. Although this interference is said to be small, $^{239}$U has to be separated from the sample prior to the neutron irradiation. Other reasons for the preirradiation separation are the possibility of using large samples and avoidance of working with high activities. A postirradiation radiochemical separation is also needed in order to remove interfering activities produced from remaining impurities during irradiation. Bromine is especially troublesome. $^{239}$Np, which can be produced by neutron irradiation of uranium, is usually used as spike to correct for the yield.

Different separation methods for neptunium have been used. $^{21}$Iron is often extracted into diisopropyl ether $^{22}$or methyl isobutyl ketone (MIBK). $^{20}$Neptunium is purified in a Dowex 1-X 4 anion-exchange column using HCl solution $^{20,23}$or nitric acid. $^{22,23}$

The postirradiation separation procedure may be the same as the preirradiation step, sometimes omitting some steps. $^{22,23}$Extraction with toluene has also been used. $^{20}$The sample may be counted as a solution.

4 STANDARDS

Calibrated standard solutions are available from several commercial suppliers. Both single radionuclides and mixtures of radionuclides may be used, depending on need. For efficiency and energy calibration of $\gamma$-spectrometers, it is useful to purchase a mixture in which the energy distribution and intensities are balanced. For energy and point-source efficiency calibration, solid radionuclide sources are convenient to use.

For $\alpha$- and $\beta$-emitting radionuclides, solutions of the individual nuclides are usually used. Those can be purchased from a number of producers of radionuclides both in Europe and the USA.

Reference samples are needed for the quality assurance program. The International Atomic Energy Agency (IAEA) and the Institute for Reference Materials and Measurements (IRMM) in Europe and the National Institute for Standards and Technology (NIST) and the New Brunswick Laboratory in the USA provide standard reference samples of different kinds.

5 QUALITY ASSURANCE

The purpose of any analysis is to obtain results, which can be used for decision making. Therefore, it is the responsibility of the analyst to ensure that the results are reasonably correct and reliable and that the precision and accuracy are known. Modern quality standards also require traceability to such a degree that control of the correctness of all data and calculations by outside persons is possible. The IAEA definition is that it is necessary to provide documentation to show that the analytical results are reliable. $^{24}$All this means that an overall plan for quality assurance has to be made and the procedures and protocols followed in all determinations of radionuclides. The international and national institutions provide all required support for this kind of activity. $^{24}$

The quality control measures are the following: use of adequate procedures and instrumentation; appropriate calibration methods; insertion of control samples in all sample measurements; control of new methods by use of standard reference samples and by analysis of the same sample with different methods; and control of overall quality by participation in national and international intercomparisons (round robins).

When a new method is developed, it has to be tested with a suitable standard reference sample. The sample matrix and the radionuclides in the reference sample must be as close as possible to the matrix and radionuclides to be measured in the real samples. If such is not available, the method should be tested by analyzing a sample with several different methods, if possible. Another method is to send a duplicate to another laboratory known for its quality.

In controlling the accuracy of routine work, the following has to be taken into account. The condition of the instruments must be checked at regular intervals. For $\gamma$-spectrometers this means that the energy calibration, resolution and efficiency must be checked for each run. This can be done by studying the spectra of the standards and control standards, which must be inserted in each run. The measured values of each parameter are compared with the original set of values. Any significant changes in the values may indicate that something is wrong. The best way to notice trends is to fill the values into a control chart. In a graphic display, trends are easily noticeable. The control level may be three standard deviations.

Control standards are always inserted into each run for general control of accuracy. A good rule is that 10% of all samples are control samples. Certified reference materials are sometimes used for this purpose. However, certified reference materials are expensive and of limited availability. Therefore, many laboratories prepare their own control samples for routine use. Reference materials
are used only occasionally, and when new methods are developed. The results obtained when analyzing the control samples are also plotted on a control chart. Intercomparisons are organized on an international scale by the IAEA and it is very useful to participate in these. The additional value from these, compared with analyzing reference materials, is that the “true” values are not known. Therefore, a more reliable indication of the true accuracy may be obtained. International intercomparisons cannot be organized very frequently, and therefore intercomparisons on a national or other less official levels can also be organized.

6 CONCLUSIONS

$^{129}$I and $^{237}$Np are critical radionuclides in considering the environmental effects of nuclear waste. They are also found in the environment as a consequence of nuclear weapons tests. In addition, $^{237}$Np may be used for the production of nuclear weapons and therefore it is a nuclide for which safeguards surveillance is necessary. For all these reasons there is a need to determine these nuclides, sometimes at very low concentrations. NAA has proven to be the most sensitive method to determine $^{129}$I and a useful method to determine $^{237}$Np in environmental samples. Therefore, NAA can be recommended as an analytical method for these nuclides, when a research reactor is available.

1 INTRODUCTION

One of the most important components of analytical chemistry involving nuclear methods is the particle detector used and associated electronics. In many cases, both of these elements prescribe the methodology of the analysis and its applicability, accuracy and limitations. Therefore, a short discussion of nuclear detection methods is essential.

This article presents a concise description of nuclear detectors such as gas-filled detectors including ionization chambers, proportional counters and Geiger counters, scintillation detectors with organic and inorganic scintillators, solid-state detectors including silicon diodes, Si(Li), Ge(Li) and high-purity germanium (HPGe) detectors, along with a short excursion into nuclear electronics and γ-ray spectroscopy. Those interested in comprehensive coverage of the subject are referred to the widely accepted standard textbook in the field by Knoll.(1)

2 NUCLEAR DETECTORS

2.1 Gas-filled Detectors

In general, detection of nuclear radiation is based on registration of the different kinds of radiative interactions with the atoms of the detector material. In most cases,
such interactions release a large number of secondary electrons, which are collected and shaped into a voltage or current pulse for subsequent analysis by electronic means.

One of the first and best-known types of nuclear detectors, based on a gas as the sensitive medium, is called a gas-filled detector. The simplest detector of this type is the ionization chamber, which can simply be regarded as a gas-filled parallel-plate capacitor. When an energetic charged particle passes through a gas inside the ionization chamber, it ionizes a large number of gas molecules or atoms along its track. As a result, electrons and positive ions are produced. The electric field between the plates is strong enough to keep the ions from recombining with the electrons and directs them in opposite directions. The negative free electrons drift toward the positive plate and the positive ions are attracted to the negative plate. When this charge is collected on the plates, an electric pulse is produced. The magnitude of the pulse is easily estimated. The average energy required to produce an electron–ion pair in dry air is about 35 eV (1 eV = 1.602 \times 10^{-19} \text{ J}). Thus, a 1-MeV charged particle produces about \(3 \times 10^6\) electron-ion pairs. For a square 10 \times 10 \text{ cm} chamber with a plate separation of 1 cm, the capacitance is \(8.85 \times 10^{-12} \text{ F}\), and therefore the resulting voltage pulse is \(1.6 \times 10^{-19} \text{ C} / \text{ion} \times 3 \times 10^4 \text{ ion} / (8.85 \times 10^{-12} \text{ F}) = 0.5 \text{ mV}\). This is a low-amplitude signal, which must be amplified before it can be analyzed by standard electronics.

If both the electrons and ions are completely collected after production of ionization by a charged particle, the final voltage signal is proportional to the total ionization and, therefore, to the charged particle energy. Usually, however, this requires too long a collection time (milliseconds). This is an exceedingly long time for handling reasonably high counting rates, hence the ion chamber is of no use in counting individual particles.

The gas in an ionization chamber should be free from electronegative impurities. Therefore, the use of air in an ion chamber is disadvantageous because air contains oxygen, an extremely electronegative gas. Ion chambers employing air have poor saturation characteristics and require high operating voltages, particularly when chambers are filled to high pressures to obtain high sensitivities. To solve this problem, some filling gas other than air have poor saturation characteristics and are filled to high pressures to obtain high sensitivities. To employ air have poor saturation characteristics and are filled to high pressures to obtain high sensitivities. Therefore, the use of air in an ionization chamber is of no use in counting individual particles.

The gas in an ionization chamber should be free from electronegative impurities. Therefore, the use of air in an ion chamber is disadvantageous because air contains oxygen, an extremely electronegative gas. Ion chambers employing air have poor saturation characteristics and require high operating voltages, particularly when chambers are filled to high pressures to obtain high sensitivities. To solve this problem, some filling gas other than air is used. The most common choice is nitrogen or an argon–nitrogen mixture for \(\gamma\)-sensitivity or hydrogen and hydrogen–argon mixture for neutron sensitivity. The gas pressure should be chosen to give an appropriate range of the charged particle, typically between 0.1 and 40 atm \((1 \times 10^4 - 4 \times 10^5 \text{ N m}^{-2})\).

Ion chambers find wide use as radiation monitors, especially in intense radiation fields. Portable ion chambers are widely used as survey instruments for monitoring \(\beta\)- and X-rays (with a \(\beta\)-shield). Radioactive gases are detected by incorporating them as a component of the filling gas of an ion chamber vented to atmosphere to allow a continuous flow of the gas to be sampled. Tritium monitoring, based on ion chambers, is also possible.\(^2\)

The main disadvantages of ion chambers are the very small output signal and the poor energy resolution compared with proportional counters and semiconductor detectors. To use a gas-filled detector, such as an ionization chamber, for detecting individual nuclear particles, the electric field in the ionization chamber must be increased significantly. In such a case, the electrons drifting to the anode can acquire kinetic energy between two successive collisions sufficient to cause the further (secondary) ionization of gas molecules. The new electrons produced by the secondary ionization are in turn accelerated towards the anode and can produce further ionization. This rapid amplification by production of secondary ionizations is called a Townsend avalanche. Provided the electric field is not too high, the total charge produced is proportional to the initial ionization of the primary particle and therefore to its energy. As a result of development of the gas-discharge avalanche, the charge collected by the electrodes may be up to \(10^4 - 10^5\) times that of the initial ionization. Because the pulse height obtained is proportional to the ionization capability of the primary particle, the device is known as a proportional counter.

A proportional counter is commonly a cylinder with a very thin wire anode coaxial to a cylindrical cathode. The electric field strength at a radius \(r\) in this geometry is given by Equation (1):

\[
E(r) = \frac{V}{r \ln(b/a)} \tag{1}
\]

where \(a\) and \(b\) are the radii of the cathode and anode, respectively. The high-field region, therefore, is concentrated very close to the anode wire. The gas multiplication takes place in this intense-field narrow region around the anode, resulting in almost total independence of the gas multiplication factor from the initial position of ionization. In general, the voltage induced on the collecting electrode by a charged particle is proportional to the fraction of voltage through which the charged particle falls before collection. Because about half of the total number of ion pairs is formed within one mean free path of the surface of the anode, the positive ions fall through a much greater potential before collection than the electrons. The signal induced on the anode therefore results mainly from the positive ions rather than the electrons. Because most of the positive ions are formed in the region of high electrostatic field near the central wire, the rise time of the signal is very rapid (of the order of microseconds) and, therefore, the
proportional counter operates at high counting rates of the order of $10^6 \text{s}^{-1}$.

Because of the gas amplification, the signal in the proportional counter is much larger than in an ion chamber. Therefore, the proportional counter is particularly useful for detecting low energy radiation and particularly photons (down to about 0.1 keV). Very thin entry windows (down to 1 µm thick) of plastic, mica or beryllium are employed in these counters. The gas filling of a proportional counter is selected from the noble gases neon, argon, krypton and xenon. In addition, up to 10% of a quench gas (methane is most commonly used) is added to stabilize the operation at high values of gas multiplication. The most common, general purpose, proportional counter is filled with a mixture of 90% argon and 10% methane, known as P-10 gas. Proportional counters for detecting $\gamma$-photons by absorption within the gas are filled with the inert gases of higher atomic number ($Z$) (krypton or xenon).

Proportional counters are designed in sealed tube configuration or as windowless flow counters. In the latter case, the radioactive sample to be counted is introduced directly into the sensitive volume of the detector. The advantage of such counting is obvious—there is no need for an entrance window which otherwise would considerably attenuate or even prevent soft radiations, such as $\alpha$-particles or low-energy photons, from entering.

With the development of highly stable high-gain amplifiers, proportional counters are the best choice for routine low-level activity sample measurements. Because of their high collection efficiency, gas proportional detectors are unsurpassed for extremely low-level radiation measurements. Because sensitivity is one of the most significant parameters for low-level monitoring, the proportional counter surface area should be considerable. The $\alpha/\beta$-counting systems designed specifically for extremely low activity samples use a large diameter (up to 5.7 cm) gas flow proportional detector with an ultrathin window for maximum efficiency or a sealed proportional detector for less stringent requirements.\(^{(3)}\)

Proportional counters are used in XRFA, especially if only one element is to be determined and provided that the matrix under consideration does not contain interfering elements. In such a case, the resolution considerations are of minor importance and the peak-to-background ratio becomes the most important factor. Argon is the most commonly used filling gas for the detection of low-energy X-ray photons, and krypton or xenon for higher energies.

If the electric field in a proportional counter is increased to even larger values, a new factor plays an increasingly important role. This factor is a considerable excitation of the gas atoms and molecules. As a result of very fast de-excitation of these molecules, ultraviolet (UV) photons are emitted that, in turn, produce photoelectrons mostly from the counter wall. These photons migrate far from the place of the original avalanche, causing secondary avalanches by photoelectrons, and so the gas in the entire tube is involved in the discharge. As a result, the amplification is very large, up to $10^{12}$. Because the entire active volume (gas) of the tube participates in every registration effect, the amount of charge collected on the electrodes is independent of the initial ionization and, virtually, a single primary ion pair can fire the discharge. As a result, there is no information at all on the type and energy of the original radiation. This region of operation is called the Geiger–Müller region, and gas counters employing this principle are usually known as Geiger–Müller counters (or simply Geiger counters).

Just after beginning the gas discharge in the Geiger counter, the electrons, being considerably more mobile than positive ions, are effectively collected by the anode, so that the output signal consists mainly of the electrons from the many avalanches. The electron collection time is of the order of a few microseconds. During this short interval, the positive ions, having a lower mobility, barely move away from the avalanche region around the anode. They are left in the counter as a positive charge sheath, which continuously builds up and reduces the electric field intensity in the counter to a level which eventually terminates the multiplication process. The discharge would then be ended after the positive ion sheath arrives at the cathode. However, when the positive ions arrive at the cathode, they cause photon emission, which in turn causes the gas discharge in the counter to start again. To prevent this from occurring, some method of quenching of the discharge must be used.

In general, quenching is implemented by external electronic means or by adding a second type of gas (quenching gas) to the tube. In electronic quenching, some reduction in the counter operating voltage is brought about immediately after the counter pulse appears. The reduction must be enough to bring the counter voltage below the starting point of the second discharge. After allowing time for all the positive ions to reach the cathode and become neutralized (up to 1 ms), the voltage is restored to its original working value.

In the so-called self-quenching counters, the quenching action is accomplished by the addition, to the main (counting) gas, a small amount of a second gas with complex molecules, with a lower ionization potential than the simple counting gas molecules. In addition, when ionized, the quenching gas should have a higher probability of losing its energy by dissociation rather than by emission of UV photons. A typical filling for a Geiger counter is 90% argon and 10% ethanol. As the positive charge sheath, consisting mostly of argon ions, begins to move towards the cathode, collisions occur.
with the molecules of the quenching gas, transferring an electron from the ethanol molecule to an argon ion. Thus, only ions of the quenching gas reach the cathode and are neutralized there. However, the energy of the ions that formerly went into emission of a UV photon is now absorbed in the dissociation of the ethanol molecule (a process not possible for a simple argon atom). The quenching gas is thus gradually used up, and the Geiger tube life expectation will be about \(10^8 - 10^9\) counts. Another widespread category of Geiger tubes is the so-called halogen counters. Their counting gas is composed of noble gases (Ne, Ar or Kr) with a small quantity (0.1–1%) of halogen vapor (Cl\(_2\), Br\(_2\) or I\(_2\)) as a quenching agent. As in the previous case, the diatomic molecules of the halogen gas are dissociated in the quenching process, but the subsequent spontaneous regeneration of the dissociated halogen molecules eliminates, in principle, the need to replace the Geiger tube. However, contamination of the quench gas by reaction products and changes on the anode surface ultimately limit the lifetime of the halogen gas are dissociated in the quenching process, and the subsequent spontaneous regeneration of the dissociated halogen molecules eliminates, in principle, the need to replace the Geiger tube. However, contamination of the quench gas by reaction products and changes on the anode surface ultimately limit the lifetime of the halogen gas. As in the previous case, the diatomic molecules of the halogen gas are dissociated in the quenching process, but the subsequent spontaneous regeneration of the dissociated halogen molecules eliminates, in principle, the need to replace the Geiger tube. However, contamination of the quench gas by reaction products and changes on the anode surface ultimately limit the lifetime of the halogen gas. As in the previous case, the diatomic molecules of the halogen gas are dissociated in the quenching process, but the subsequent spontaneous regeneration of the dissociated halogen molecules eliminates, in principle, the need to replace the Geiger tube. However, contamination of the quench gas by reaction products and changes on the anode surface ultimately limit the lifetime of the halogen gas.

In the period immediately following the Geiger discharge, the positive space charge around the anode effectively reduces the electric field below the ignition point. If another charged particle occurs inside the counter during this period of time, it is not observed, because gas multiplication is prevented. This dead time when the tube is unable to respond to radiation is of the order of 50–200 \(\mu\)s. After the dead time there is a progressive recovery when the Geiger counter can respond again but the resulting pulse does not attain its normal magnitude. Registration of such a partial pulse depends on the sensitivity adjustment of the counting electronics. The usual procedure is to arrange the electronic circuit with a defined dead time so that the loss of counts from finite dead time is accurately estimated.

The counting efficiency of the Geiger counter for any charged particle that enters its active volume is close to 100%, because even one charged particle inside the tube is enough to trigger full-scale Geiger discharge. The efficiency for counting \(\gamma\)-rays depends on the probability of interaction of the incident \(\gamma\)-ray with the solid wall of the counter and on the probability that the secondary electron released in this interaction reaches the active volume before the end of its track. Because the probability of \(\gamma\)-interaction within the sensitive layer is small even for high-Z cathode materials, \(\gamma\)-ray counting efficiency is generally low and at 1 MeV is about 1%. Most Geiger counters have a cylindrical stainless-steel cathode and a mica window thickness down to 1.5 mg cm\(^{-2}\); gas pressure of the order of 100 Torr (1.33 × 10\(^4\) N m\(^{-2}\)) is usual.

Geiger counters are used where simple, portable, inexpensive and rugged radiation detectors are needed. A large variety of Geiger counters are available for different applications, including the detection of \(\alpha\)-, \(\beta\)- and \(\gamma\)-radiation in separate or mixed radiation fields. Many types of radiation survey meters used in X-ray and \(\gamma\)-monitoring consist of an energy-compensated Geiger tube, a portable high-voltage power supply and counting electronics. They are ideally suited for detecting different radiation levels from radioactive sources and radiation contamination and in X-ray machines in both industrial and hospital environments.

The various operating regions of gas-filled detectors are presented in Figure 1. The amplitude of the observed pulse is given as a function of the applied voltage within the detector for two particles depositing two different amounts of energy within the gas. At very low voltages, the field is insufficient to prevent the recombination of the primary electrons and ions, and the collected charge is less than the original one. As the voltage is increased, recombination is suppressed and the region of ion saturation is achieved. This is the ionization chamber region, where the pulse output is proportional to the primary ionization and thus to the energy of the radiation, but is independent of the applied voltage. As the voltage is increased still further, gas multiplication begins in the detector and the observed pulse amplitude increases substantially with the applied voltage. This is the proportional region, in which the pulse amplitude is given for charged particles of two different energies: (E and 2E): A, pulse amplitude reduced by recombination; B, ionization chamber region; C, proportional counter region; D, limited proportionality region; E, Geiger counter region; F, continuous discharge region.

![Figure 1 Pulse amplitude as a function of applied voltage for the different operating regions of gas-filled detectors. Plots are given for charged particles of two different energies (E and 2E): A, pulse amplitude reduced by recombination; B, ionization chamber region; C, proportional counter region; D, limited proportionality region; E, Geiger counter region; F, continuous discharge region.](image-url)
pulse amplitude rises proportionally to the voltage, but the output pulse remains proportional to the energy of the radiation, thus simplifying identification of the primary radiation and its energy. Further increase of the applied voltage results in increasing concentration of positive ions (space charge) around the anode, which significantly diminishes the electric field within the detector. As a result, some nonlinearities in gas multiplication begin to be observed. This is the region of \textit{limited proportionality}, in which the pulse amplitude still increases with energy of the primary radiation, but not linearly. Finally, as the applied voltage becomes sufficiently high, gas multiplication is determined by the space charge created by the positive ions. Under these conditions, the gas discharge is self-limiting and all output pulses are of the same amplitude, regardless of the kind of primary radiation and its energy. This is the \textit{Geiger–Müller region} of operation characteristic of Geiger counters. For more detailed information on the subject of gas-filled detectors, see general reference books.\footnote{4–6}

2.2 Scintillation Detectors

2.2.1 Basic Principles

The main disadvantage of gas-filled detectors is their low efficiency for several types of nuclear radiation and particularly for $\gamma$-rays. This arises from the fact that the gas detection medium is low in density. From this point of view, solid detectors are more advantageous, because their higher densities result in acceptable absorption probabilities for detectors of reasonable size. Of the detectors with a solid detection medium, the scintillation counter is one of the earliest and most widely used detectors of nuclear radiation. A schematic representation of the basic elements and processes in a scintillation detector is given in Figure 2. The detector consists of a detection medium (scintillator) and a PMT. The incident particle enters the scintillator and interacts repeatedly with the atoms of the scintillator, raising them to excited states. De-excitation follows very rapidly by emission of photons of visible or near-visible light. The emitted photons strike a photocathode, releasing a maximum of one photoelectron per photon. Finally, these photoelectrons are multiplied in the PMT, resulting in an output signal pulse of up to several volts.

In general, for use as a scintillator for nuclear radiation, the material should possess the following properties:

1. should convert the energy of charged particles into emitted light linearly and with high scintillation efficiency;
2. scintillator should be transparent to its own emitted light;
3. decay time of the luminescence should be short;
4. spectral distribution of the emitted light should match as closely as possible the response of the photocathode of the PMT used.

Many materials are known to luminesce under the influence of nuclear radiation. They are in gaseous, liquid or solid form. Scintillating materials are usually divided into organic and inorganic materials. The most widely used inorganic scintillators have generally higher light output and better linearity but slower time response than organic scintillators. The high photoelectric cross-section and high density of inorganic scintillators make them especially valuable for $\gamma$-detection whereas organic scintillators are more preferable for charged particle and neutron spectroscopy. Organic scintillators in liquid or plastic form are easily fabricated in large and irregular geometries. The size of inorganic scintillators is strictly limited by the maximum size to which a single crystal may be grown.

A general review of the basic theory, practice and application of scintillation detectors can be found in the exhaustive monograph by Birks.\footnote{7} Because the mechanisms of luminescence in organic and inorganic scintillators are different, they are considered separately.
2.2.2 Organic Scintillators

The molecules in organic scintillators (whether in the gaseous, liquid or plastic state) are relatively loosely bound and, as a result, retain their individual electronic structure and luminescent features. The properties of organic scintillators can be discussed in terms of the discrete excited states of the molecules presented in simplified form in Figure 3. The electronic energy states are represented as a potential minimum. Inside the electron potential minimum is a series of levels with much finer spacing corresponding to various vibrational states of the molecule. Typical spacing of vibrational levels is about 0.15 eV, and the electronic excitation energies are of the order of 3–4 eV. A charged particle passing inside the scintillator interacts with many molecules, losing a few electronvolts at each interaction. Generally, a scintillator molecule absorbs energy either by excitation of the electrons to higher excited states, or by atoms in the molecule vibrating against one another. In Figure 3, the absorption of energy by the molecule is represented by upwards arrows. As a result of the interaction, many vibrational states also become excited. However, because any excited vibrational state is not in thermal equilibrium with its neighbors, it quickly decays (during ~1 ps) to the lowest vibrational state of the electronic excited state $S_{10}$. Therefore, as a first stage of the scintillation process, a population of excited molecules in the $S_{10}$ state is produced. De-excitation of these molecules (during a few nanoseconds) to one of the vibrational states of the ground-level electronic state produces the principal scintillation light (the downward arrows in Figure 3). The vibrational states of the electronic ground state again decay quickly to the vibrational ground state $S_{00}$.

The length of the upward arrows in Figure 3, corresponding to photon absorption energies, is greater than that of the downward arrows, corresponding to photon emission energies in a scintillator. This explains why organic scintillators are transparent to their own emission spectrum.

Of the pure organic materials, only anthracene and stilbene (aromatic hydrocarbons with a linked benzene ring structure) have achieved widespread popularity. Anthracene features the greatest light output per unit energy (scintillation efficiency). Stilbene has a lower scintillation efficiency but it exercises pulse-shape discrimination (PSD) properties to distinguish between scintillation induced by heavy charged particles (e.g. protons) and by electrons. Both materials are relatively fragile and may be fabricated as single crystals with a side of no more than several centimeters.

If a small concentration of impurity is added to a bulk scintillator (solvent), in some cases, there is high probability that the excitation energy absorbed mainly by the solvent molecules is transferred ultimately to the impurity molecules. If these molecules de-excite by radiationless transition (mainly by collisions), the process reduces the scintillation efficiency, and the effect is known as “quenching”. A prominent example is dissolved oxygen which substantially degrades the light output of many scintillators. On the other hand, if the added impurity is an efficient scintillator it may effectively increase the overall fluorescent efficiency. These binary organic scintillators, widely used in liquid and plastic form, represent a separate type of organic scintillator called liquid and plastic solutions. The primary excitation takes place mainly in the host material or solvent which may be toluene, xylene or benzene for liquid scintillators and poly(vinyltoluene) or polystyrene for plastics. The excitation is effectively transferred to solute molecules such as $p$-terphenyl, PPO (2,5-diphenyloxazole) and PBD [2-phenyl-5-(4-biphenylyl)-1,3,4-oxadiazole]. Sometimes a third additive is present in a concentration of a few percent or less and serves as a waveshifter. Its function is to improve matching between the fluorescence spectra and the PMT spectral response and to increase the transparency of the scintillator to its own light. The most commonly used waveshifter is POPP [1,4-di[2-(5-phenyloxazolyl)]benzene].

For most organic scintillators, the variation of the light output with electron energy is slightly nonlinear for low energies up to about 0.1 MeV and is linear at higher energies. Heavy charged particles, such as protons or $\alpha$-particles, are considerably less efficient in producing light in organic scintillators than electrons. This subject is extensively treated in a general reference. (7)

As to the time response of the organic scintillators, this category of scintillators is the fastest. In a simple approach, the time profile of the light pulse is described by a single exponent $I = I_0e^{-t/\tau}$, where $\tau$ is the time...
constant describing the decay of the optical levels. In the fastest organic scintillators, \( \tau = 1.5\text{–}2.5 \text{ ns} \). This exponent represents the prompt fluorescence responsible for most of the observed scintillation light. In some scintillators, however, the slower components are also observed with a characteristic decay time of several hundred nanoseconds. It should be pointed out that the relative amounts of light in the fast and slow components often depend on the nature of the exciting particle. This dependence is used to discriminate between different kind of particles. This is so-called PSD, used in several applications, but the most common use is for discrimination between \( \gamma \)-rays (i.e. via Compton electrons) and fast neutrons (i.e. via recoil protons).

2.2.3 Inorganic Scintillators

In general, inorganic scintillators are single-crystal insulated materials. A monocrystalline structure is necessary because multiple scattering and absorption of the emitted light at the many faces of a polycrystal would make such a scintillator useless. The energy band structure of a crystalline scintillator includes the lower band, called the valence band, which is generally full and represents the energy states of the electrons strictly bound at crystal sites. The upper band, called the conduction band, contains empty energy states. The forbidden energy band, in which electrons can never be found, is between the valence and conduction bands. In inorganic scintillators, the width of the forbidden band is about 4 eV. Incoming radiation can excite an electron and elevate it from the full valence band across the forbidden band into the conduction band. In the pure crystal, the excited electron loses its energy by emitting a photon and returns into the valence band. Although pure inorganic crystals are used as scintillators, they are inefficient because of the high self-absorption of the emitted light by the crystal itself. To reduce self-absorption of the light and to increase the probability of visible photon emission, a small amount of a suitable impurity, called an activator, is added to the crystal. Such activators create additional energy states within the forbidden band and photon emission takes place between the activator states. Because the photon energy is less than the forbidden bandwidth of the host material, self-absorption cannot occur and the scintillation process results in emission of photons of lower energy lying in the visible range. Another advantage of the change in photon energy from the UV (pure crystal) to the visible (activated crystal) results in a better overlap between the emission spectra of inorganic scintillators and the photosensitivity of most photocathodes.

The most notable property of inorganic scintillators is their high efficiency for detecting \( \gamma \)-rays. This follows from the higher density and higher atomic number of inorganic scintillators, resulting in much more efficient detection by the photoelectric effect than in any organic material. Of the inorganic scintillators, the most common material is sodium iodide to which 0.1% mole fraction of thallium is added as an activator. Such NaI(Tl) crystals have a high light yield. They are fabricated in irregular shapes and in large sizes, up to 30 cm. Sodium iodide is deliquescent and therefore must be encapsulated in an airtight container for normal use. The dominant decay time of the scintillation of NaI(Tl) is long (\( \approx 230 \text{ ns} \)) compared with that of organic scintillators and it is therefore not chosen for applications requiring high counting rates and fast timing. The response of the NaI(Tl) crystal to \( \gamma \)-rays (via the photoeffect) is virtually linear over the practical energy range. This feature, in addition to its excellent light yield, makes for NaI(Tl) the generally accepted standard scintillator for \( \gamma \)-ray spectrometry.

Of other inorganic scintillators, CsI(Tl) and CsI(Na) have become popular for use as \( \gamma \)-detectors. Both crystals have a higher effective atomic number than NaI(Tl) and as a result their \( \gamma \)-ray absorption coefficient is higher. Cesium iodide crystals are less brittle than NaI(Tl) and are not as hygroscopic. CsI crystals can be cut into thin sheets of thickness only sufficient enough to stop heavy charged particles. Because of its low sensitivity to \( \gamma \)-rays and electrons, this configuration is ideally suited for detecting heavy charged particles.

Silver-activated zinc sulfide [ZnS(Ag)] is another inorganic scintillator used for the detection of \( \alpha \)-particles and heavy ions. It has a very high luminescent efficiency but is only available as a multicrystalline powder with a limited opacity to its own light. For detecting heavy charged particles, the ZnS(Ag) powder is dispersed as a thin layer (scintillation screen). It is effectively used for fast neutron detection by the proton recoil method. In such a case, a detector is a dispersion of zinc sulfide in a hydrogogenous medium.

Of the recently developed inorganic scintillation materials, bismuth germanate (Bi\(_4\)GeO\(_{12}\)) (BOG) cannot be omitted. It was first introduced commercially in 1979. Its prominent feature is a high stopping power (\( Z \) of Bi = 83, density = 7.13 g cm\(^{-3}\)), resulting in the highest probability of any scintillator for the photoelectric absorption of \( \gamma \)-rays. The light yield is relatively low, only \( \sim 21 \% \) of that of NaI(Tl). This factor limits low energy applications of BOG and impairs its energy resolution. Therefore, BOG is chosen when the need for high \( \gamma \)-ray counting efficiency outweighs consideration of the energy resolution. The principal decay time of BOG is 300 ns, close to that of NaI(Tl); however, the slower decaying components responsible for the afterglow are more than 100-fold weaker than those in sodium iodide. This feature, together
with the high γ cross-section of BGO and its nonhygroscopicity, have led to widespread application of BGO as a scintillation scanner in computerized tomography and subsequently in positron emission tomography. In both cases, scintillators must accurately follow rapid changes in photon intensity.

The properties of some most commonly used scintillators are presented in Table 1.\(^1\)\(^,\)\(^2\)\(^,\)\(^8\)

### 2.2.4 Photomultiplier Tubes

A schematic diagram of a PMT is presented in Figure 2. It consists of a photocathode, a series of multiplying and focusing electrodes called dynodes and a collector electrode, or anode. A small number of photoelectrons released from the photocathode by the scintillation light are accelerated (and focused) through 100–200 V on to the first dynode. The dynodes are made of alloys having a high probability of secondary electron emission. As a result, an increased number of secondary electrons (a typical value is 4–6 for every primary incident electron) is produced by the first dynode and these, in turn, are accelerated on to the second dynode, where further multiplication takes place. The process of multiplication is repeated on each dynode. If a PMT has \(N\) multiplication stages (dynodes) and the multiplication factor for a single stage is \(\delta\), then the overall gain \(K\) for the PMT is given by Equation (2):

\[
K = \alpha \delta^N
\]

where \(\alpha\) is the fraction of all photoelectrons collected by the multiplier structure (typically \(\alpha \approx 1\)). A common number of stages is 9–14. With typical value of \(\delta = 5\), this results in an overall gain of \(10^6\)–\(10^9\) at the anode. This high gain is sufficient to produce a pulse of several volts on the anode without any external amplification. The multiplication factor \(\delta\) varies (and generally increases) with the interdynode voltage. Therefore, the overall gain \(K\) is a very sensitive function of the high voltage applied to a PMT.

One of the important elements of a PMT is the photocathode, which is responsible for converting incident light photons into photoelectrons. The photocathode is deposited as an opaque or semitransparent layer on the inside of the glass envelope. Historically, the most popular photocathode material was a compound of antimony and cesium which gave a peak sensitivity to light at \(\sim 350\) nm and a high quantum efficiency (i.e. number of photoelectrons emitted per incident light photon) of up to 23%. In more recent years, a multialkali photocathode (Na\(_2\)KSb activated with Cs) was developed. This photocathode is sensitive from the UV to the red and near-infrared regions of the spectrum and has a high quantum efficiency of up to 30% in the blue region. The multialkali photocathodes have a limited upper temperature range of about 50 °C. Of bialkali photocathodes, \(K\_\text{CsSb}\) has an even higher peak quantum efficiency. Another prominent feature of the bialkali photocathodes is their significantly lower thermoionic emission than the multialkali or Cs–Sb photocathodes. When a PMT is operated even in complete darkness, electrons are still emitted from the photocathode primarily because of the thermoionic effect. The resulting dark current is amplified by the PMT and sets a limit to the smallest signal observable by the PMT. For this reason, the bialkali photocathodes are preferable to the others.

Materials such as BeO, MgO and Cs\(_3\)Sb have been used (\(\delta \approx 5\) at typical accelerating voltages between dynodes of 200–300 V) for the electron-emitting surface of the dynodes. More recently, gallium phosphide (GaP) was introduced as a material for the dynode emitting surface, particularly for the first dynode. The multiplication factor \(\delta\) of GaP material is considerably higher, close to 10 at 200 V, and goes up to 50 at a 1000 V interstage voltage. This feature is valuable in PMT for ultrafast timing applications.

The coupling of a scintillator to a PMT is achieved in many ways. Some detectors integrally connect the PMT to the scintillation crystal enclosed in a light-tight assembly. Others incorporate the scintillator in one container with the PMT mounted so that it can be removed by the user.

and reinstalled. In any case, transparent optical grease should be used between the scintillator and the PMT to provide a smooth change in refractive index and minimize internal reflection. Scintillators are mounted directly on the PMT face plate or optically coupled by a light pipe typically made of quartz or glass. Light pipes enhance uniform light collection or when the PMT must be located far from the scintillator. Both the scintillator and the light pipe must be painted with reflective material to enhance light collection. Magnesium oxide is the most commonly used reflective material.

2.2.5 Application of Scintillation Detectors in Analytical Chemistry

Liquid scintillators are often used as large-volume detectors with dimensions of up to several meters. In such applications the liquid scintillator may be the only choice from a price standpoint. However, probably the most common application of liquid scintillators is in assaying radioactive material which can be dissolved or dispersed in the scintillator solution. In this case the scintillator acts as a very efficient detector for the emitted charged particles. This so-called liquid scintillation counting method is especially valuable for counting of low energy β-rays of tritium ($E_{\beta}^{\text{max}} = 18$ keV) and $^{14}$C ($E_{\beta}^{\text{max}} = 160$ keV). Liquid scintillation counting can also be used for α-active samples with an efficiency close to 100%. Because the α-particle energies from radionuclides are high enough (between about 2 and 11 MeV), the light output is much greater than in the case of low-energy β-particle counting. Therefore, pulse-height discrimination is easily applied to reject β- or low-energy γ-induced effects. The high-energy γ-background is eliminated by PSD. Because of very high counting efficiency, background discrimination possibilities and uniform counting geometry, liquid scintillators are extensively applied for counting low-level activity samples.

Because plastic scintillators are relatively inexpensive, they can be used in large-volume solid scintillator detectors and in a large variety of forms (flat sheets, rods, cylinders, etc.). The α- or β-particle detectors are manufactured by optically cementing a thin plastic scintillator sheet to a thermoplastic light-guide disk. Because of their low sensitivity to γ-radiation (low Z), these detectors are ideally suited to low-level monitoring of α- and β-particles, heavy ions, fission fragments, etc. Another α-particle detector, which features low sensitivity to γ-radiation and large light output, is based on ZnS(Ag) phosphor. The detector consists of a thin layer of ZnS(Ag) bonded to a Perspex thermoplastic disk 6.4 mm thick. The phosphor layer is covered by double aluminated plastic film, permitting use of the detector in full illumination.\(^9\)

In general, organic scintillators are used for the detection and spectrometry of charged particles (electrons, protons, α-particles, etc.). As such they are widely used for the detection and spectrometry of γ-rays through the Compton electrons and of fast neutrons through recoiled protons. To expand the detection possibilities of both liquid and plastic organic scintillators, it is possible to load them with some additional materials. Thus, for instance, boron, lithium or gadolinium is added to give a thermal neutron detector. In the case of boron and lithium, the (n,α) reaction results in direct detection of α-particles in the organic scintillator. In the case of gadolinium, effective capture for thermal neutrons results in β- and γ-activity which is detected in the organic scintillator.

For inorganic scintillators, the scintillation detector most frequently used is the sodium iodide crystal activated with thallium, referred to as NaI(Tl). In many applications involving low-level counting systems, where α-, β-, and γ-rays must be acquired simultaneously from the same sample, an NaI(Tl) detector should be incorporated in the shield assembly to take advantage of coincidence methods to reject background events as much as possible.

Recently, the monitoring of radon and radon progeny levels in households has become of increasing interest. Radon-222 is an inert gas coming from radium-226, has a half-life of 3.8 days and is an α-emitter. Radon is the heaviest known gas and it is ubiquitous in soil and air. The main hazard of radon is from inhalation of the element and its solid daughters, which are collected on dust in the air. Radon accounts for roughly 50% of the total background exposure. The US Environmental Protection Agency (EPA) recommends remediation action if the concentration of radon is consistently above 150 Bq m\(^{-3}\).\(^{10}\)

One of the techniques widely used for radon monitoring is based on the routine screening of radon levels in air by counting γ-rays coming from the radon progeny nuclides captured in activated charcoal canisters.\(^{11}\) A 7.6 × 7.6 cm (3 × 3 in) NaI(Tl) detector in a benchtop, low-background lead shield is used to accommodate charcoal canisters for counting the radon daughters, such as $^{214}$Pb ($E_{\gamma} = 242, 295$, and 352 keV) and $^{214}$Bi ($E_{\gamma} = 609$ keV). Depending on its moisture content, charcoal effectively absorbs radon at a predictable rate. By weighing the canister before and after exposure to radon, the amount of adsorbed water is determined. Knowledge of this and the exposure time allows a calibration to be made so that the level of radon daughters captured on the cartridge is converted into the average radon concentration in the air during exposure. The charcoal canister method is within the ±25% error band considered acceptable by the EPA.\(^{12}\)

Medium-size NaI(Tl) detectors [5 × 5 cm or 7.6 × 7.6 cm (2 × 2 or 3 × 3 in)] and multiple detector
configurations (up to 64 sodium iodide detectors) are widely used for foodstuff monitoring, especially after the Chernobyl nuclear accident. Foodstuff monitoring is based on routine screening of solid and liquid foodstuffs. It is intended primarily for the quantitative assay of radioactive contamination of foodstuffs by γ-emitting radioisotopes, such as 137Cs ($E_γ = 662$ keV) and 134Cs ($E_γ = 605, 796$ keV). To count a foodstuff or any other sample in the optimum and reproducible geometry with a minimum background, the sample should be placed in a Marinelli (re-entrant) beaker surrounding the sodium iodide detector, which is, in turn, placed inside a low-background lead shield. The sodium iodide-based foodstuffs monitor may also be used in other low-level counting applications, such as radon charcoal filter counting, test swipes counting, water monitoring and material monitoring.

Large-size [up to $10 \times 10 \times 40$ cm ($4 \times 4 \times 16$ in)] NaI crystals with integral PMTs are used in whole-body counters for rapid (~1 min) subject screening. They provide excellent sensitivity for quantitative analysis of fission and activation products at nuclear facilities, such as 60Co, 137Cs, 134Cs, 131I, 133I, 54Mn and 95Zr. Another application field for the large NaI(Tl) or CsI(Na) scintillation crystals is the aerial survey. Radiation detectors are carried on planes or helicopters which cover large areas in relatively short time intervals. The detectors are used to detect γ-rays of $40$K ($E_γ = 1461$ keV) or daughters from the uranium or thorium radioactive series.

NaI(Tl) detectors are often used in the form of a well detector, that is, the scintillation crystal is shaped to form a cavity. Surrounded by the detector element, such a well is highly efficient in measuring small samples, because the radioactive samples are placed directly in the crystal well.

The high efficiency NaI(Tl) and BGO inorganic scintillators are widely used in NAA, both prompt (PNAA), where measurements of emitted photons occur during the neutron irradiation, and delayed DNAA, where measurements occur following radioactive decay. In this application, both scintillators have the advantage of where measurements occur following radioactive decay. During the neutron irradiation, and delayed DNAA, scintillators are widely used in NAA, both prompt and delayed. An NaI detector, which has much higher efficiency than the gas-filled proportional counter, can be effectively used as an X-ray detector in XRFA, especially in the cases when one element has to be determined and provided that the matrix itself does not contain interfering elements.

2.3 Semiconductor Detectors

2.3.1 Introduction

Historically, semiconductor detectors were developed as solid-state ionization chambers. Highly insulating diamond crystals were first used as a sensitive material (instead of gas) to obtain a high-field, low-current, solid-state device for detecting nuclear radiation. However, such crystals were quickly abandoned because of inadequate charge collection characteristics of the diamond crystals resulting from the charge trapping at defect centers. Only after the successful development of the technology for the production of highly purified single crystals of silicon (Si) and germanium (Ge) for transistors did it become possible to develop Si- and Ge-based solid-state detectors by forming reverse-biased junctions on these materials. The most prominent feature of the semiconductor detectors is their excellent energy resolution. In addition, they have fast timing capabilities, and their effective thickness and thus their efficiency are varied in accordance with the requirements of the experiment. Detailed information on the subject of semiconductor detectors is available in the current literature.$^{1,14-17}$

2.3.2 Basic Principles

At first sight, it seems that many solids could be used as the sensitive material in solid-state detectors, but this is not so, for a number of reasons. First we have to take into account the noise considerations. Even in the absence of radiation, the conductivity of the active volume is not negligible, so that inevitably a nonzero leakage current across the surface of the solid-state detector exists and obscures the small useful signal. From this point of view, insulators (with resistivity of up to $10^{10}$ $\Omega$ cm) are the best choice. However, insulators suffer from such grave shortcomings as charge carrier trapping and formation of a space charge. Under these circumstances, the electrons and holes formed in an insulator would quickly be trapped or recombine and so would induce only a negligible voltage pulse on the detector electrodes. Therefore, semiconductors are the more appropriate choice for solid-state detectors, despite the fact that their resistivity under normal conditions is considerably less than that required by signal-to-noise ratio considerations ($\sim 10^{10}$ $\Omega$ cm). Of all semiconductor materials, germanium and silicon further exceeds that of the NaI(Tl) scintillator by another factor of 10 at $E_γ > 8$ MeV.$^{13}$
are used almost exclusively in the modern solid-state detectors, because adequate purification technology is available only for these materials. Using this advanced purification technology, silicon and germanium with resistivity of no more than about 50 000 and 50 Ω cm, respectively, are obtained. Both values are too small to allow the straightforward application of a homogeneous block of Si or Ge as a semiconductor detector. Therefore, some special measures are taken to increase sharply the resistivity of the semiconductors. These measures include cooling the semiconductor to liquid nitrogen temperature (77 K), use of a reverse biased p–n junction, compensation by the lithium drift method and other means that will be elaborated later.

2.3.3 Physical Properties of Pure Germanium and Silicon

Both Ge and Si have a crystal structure consisting of a regular repetition of a tetrahedron unit cell with an atom at each vertex. Each atom in such a structure contributes four electrons, so that the atom is tetravalent. The connection between neighboring atoms stems from the fact that each of the four valence electrons of a Ge or Si atom is shared by one of its four adjacent neighbors. This is the so-called electron-pair, or covalent, bond. Because all four valence electrons take part in binding of one atom to another, no free carriers of electricity are available and the crystal behaves as an insulator, at least at very low temperatures (close to 0 K). In such a pure crystal, an electron is allowed to exist only in the valence band, where it is immobile, or in the conduction band, where it is free to move in an applied electric field. At 0 K the width of the forbidden band \( E_g \) is 1.21 and 0.78 eV for Si and Ge, respectively. Energies of this magnitude normally cannot be acquired from an applied electric field. Therefore, at absolute zero, the valence band remains full, the conduction band stays empty and the crystals are insulators. As the temperature is raised, an increasing number of the valence electrons can acquire energy greater than the forbidden bandwidth \( E_g \) and thus transfer into the conduction band. Once in the conduction band, these electrons are free to move under the influence of an applied electric field. The elevation of an electron to the conduction band leaves a vacancy in the valence band. This vacancy is known as a positive “hole” which under the influence of an electric field will move in a direction opposite to that of the electron. The field-induced motion of both electrons and holes contributes to the overall conductivity of the semiconductor. The production of equal amounts of conduction electrons and holes by thermal agitation is known as the intrinsic mechanism of conductivity. In an intrinsic semiconductor, the number of holes \( p \) is equal to the number of free electrons \( n \). Whereas thermal excitation produces new hole–electron pairs, other hole–electron pairs disappear as a result of recombination. It is found that the intrinsic concentration \( n_i (n = p = n_i) \) varies with temperature \( T \) according to Equation (3):

\[
n_i = AT^{3/2}e^{-E_g/2kT}
\]

where \( E_g \) is the forbidden bandwidth at 0 K in eV, \( k \) is the Boltzmann constant in eV K\(^{-1}\) and \( A \) is a constant (\( A = 1.8 \times 10^{16} \text{ cm}^{-3} \) for Si and \( 8.5 \times 10^{15} \text{ cm}^{-3} \) for Ge). From Equation (3) it follows that the intrinsic hole or electron concentrations at 300 K are \( 1.5 \times 10^{10} \text{ cm}^{-3} \) in Si, and \( 2.5 \times 10^{13} \text{ cm}^{-3} \) in Ge. Another important conclusion is that the equilibrium intrinsic concentration, being an exponential function of temperature, decreases sharply as the material is cooled.

If an electric field is applied to the semiconductor material, the charge carriers (free electrons and holes) start to drift in the direction dictated by the field. Because of the inevitable inelastic collisions with ions of the crystalline lattice, a steady-state condition is reached in which an ultimate value of drift velocity is attained. This drift velocity \( v \) is proportional to both the applied field \( E \) and the mobility of the charge carriers (Equations 4a and 4b):

\[
v_h = \mu_h E \\
v_e = \mu_e E
\]

where \( \mu_h \) and \( \mu_e \) are mobilities of holes and free electrons, respectively. These particles move in opposite directions under the influence of the applied field \( E \), but because they are opposite in sign, both currents are in the same direction. Hence the total current density \( J \) is given by Equation (5):

\[
J = (n\mu_e + p\mu_h)qE = \sigma E
\]

where \( n \) and \( p \) are the concentrations of free electrons and holes, respectively, and \( \sigma \) is the conductivity. Therefore, we have Equation (6):

\[
\sigma = \frac{1}{\rho} = (n\mu_e + p\mu_h)q
\]

where \( \rho \) is the resistivity of the semiconductor. The mobility \( \mu \) is a function of temperature and electric field intensity.\(^{18}\) It varies as \( T^{-m} \) over a temperature range of 100–400 K. For Si, \( m = 2.5 \) (2.7) for electrons (holes), and for Ge, \( m = 1.66 \) (2.33) for electrons (holes). With regard to the dependence on the electric field intensity, the mobility remains constant up to approximately \( 10^3 \text{ V cm}^{-1} \). At higher electric field values, the mobility decreases with increase in \( E \), and the carrier speed approaches a constant value of the order of \( 10^7 \text{ cm s}^{-1} \) (saturation velocity).
The forbidden bandwidth $E_g$ in semiconductor also depends on temperature.\cite{18} Experimentally, for Si, we have Equation (7):

$$E_g(T) = 1.165 - 1.66 \times 10^{-4} T$$

(7)

and at room temperature (300 K), $E_g = 1.11$ eV. Similarly, for Ge, we have Equation (8):

$$E_g(T) = 0.746 - 2.70 \times 10^{-4} T$$

(8)

and at room temperature, $E_g = 0.66$ eV.

The main constants describing the most important physical characteristics of Ge and Si are given in Table 2.\cite{11,19}

In gas-filled detectors, the mobility of free electrons is typically 1000 times greater than that of ions, but in semiconductor materials the mobility of the holes is comparable to that of the electrons (see Table 2). As a result, the holes contribute a significant part of the overall conductivity and so improve considerably the timing characteristics of semiconductor detectors. Moreover, as shown in Table 2, the mobilities of the charge carriers increase by an order of magnitude at the temperature of liquid nitrogen (77 K). Thus the timing characteristics of semiconductors are improved even more by cooling to this temperature. As a result, semiconductor detectors are expected to be among the fastest of all radiation detectors.

From Equations (3) and (6) it follows that the resistivity of semiconductor materials increases very rapidly with cooling. Calculations based on Equations (3) and (6) and data presented in Table 2 show that the intrinsic resistivity of absolutely pure (i.e. without any impurities) Ge and Si increases at 77 K to such an extent that both materials are excellent insulators at this temperature.

It may appear at first sight that either material could be successfully used at low temperatures to form the basis of a homogeneous solid-state detector. However, in practice any semiconductor material inevitably contains some small amounts of impurities which cannot be removed by the most advanced contemporary purification technologies. Moreover, the electrical properties of real semiconductor materials are largely dictated by these very small amounts of residual impurities. The intrinsic semiconductor is a very useful theoretical concept but in practice it is virtually unattainable.

### 2.3.4 Physical Properties of Real (Doped) Germanium and Silicon

The effect of the small concentration of impurity present in semiconductor material should be considered, either as a residual amount after the best purification possible or as a small amount intentionally added to the material to change its properties. If a small percentage of trivalent or pentavalent impurity atoms is added to tetravalent Si or Ge, a doped, impure or extrinsic semiconductor is formed. The impurity atoms displace some of the host atoms in the crystal lattice. If the dopant atom has five valence electrons, four of the five electrons occupy covalent bonds; the fifth is bound only very loosely to the original impurity atom and, as a result, will be available as a carrier of current. The energy required to detach the fifth electron from the atom is very small, of the order of 0.01 eV for Ge and 0.05 eV for Si. Suitable pentavalent impurities are P, As and Sb. Because such impurities donate excess negative charge carriers (electrons), they are referred to as donor, or n-type, impurities, and the semiconductor material containing them is called an n-type semiconductor. Donor impurities introduce a set of

</table>
discrete donor states just slightly below the conduction band. Because the energy spacing between the donor levels and the bottom of the conduction band is very small (0.01 eV for Ge and 0.05 eV for Si), almost all of the donor impurities are ionized at room temperature (Equation 3), and therefore, almost all the excess electrons of the donor atoms are raised into the conduction band. Because in most practical cases the impurity atoms are present in concentrations of the order of a few parts per million, the concentration of impurity atoms \( N_D \) is large compared with the concentration of intrinsic electrons \( n_i \). Therefore, the free electron concentration in an n-type material becomes completely dominated by the contribution from the donor atoms \( (n \approx N_D) \). In an n-type semiconductor material, the number of electrons increases and the number of holes decreases, because the larger number of electrons present increases the rate of recombination of electrons with holes.

On the other hand, if a trivalent impurity, such as In, B or Ga, is added to an intrinsic semiconductor, only three of four covalent bonds are formed, leaving a vacancy (hole) in the fourth one. These impurities are known as acceptor, or p-type, impurities. They introduce discrete acceptor states just above the valence band, and the material itself is referred to as a p-type semiconductor because the principal charge carriers are the positively charged holes. Just as in the case of the donor impurity, only a very small amount of an acceptor must be added to change appreciably the conductivity of the semiconductor material. The ionized acceptor sites represent fixed negative charges, which balance the excess hole charges and do not take part in current conduction in the semiconductor. Usually the concentration \( N_A \) of acceptor impurities is made large enough to be compared with the intrinsic concentration of holes \( p_i \). In such a case the number of holes is totally determined by the concentration of acceptors \( (p \approx N_A) \). As mentioned above, n-type impurities decrease the number of holes. Similarly, doping with p-type impurities considerably decrease the concentration of free electrons. The mass-action law controls the number of the free charge carriers in the semiconductor. It states\(^{(18)}\) that, under thermal equilibrium, the product of the number of free negative \( (n) \) and positive \( (p) \) concentrations is a constant, independent of the amount of donor and acceptor impurity doping (Equation 9):

\[
n_p = n_i^2 \quad (9)
\]

where \( n_i \) is the intrinsic concentration given by Equation (3). The important result following from Equation (9) is that the doping of an intrinsic semiconductor increases the conductivity, and also produces a material in which the electric carriers are either predominantly holes or predominantly electrons. In an n-type semiconductor, the electrons are called the majority carriers and the holes are called minority carriers. In a p-type material, the holes are the majority carriers and the electrons are the minority carriers.

In practice, a semiconductor material always contains both types of impurities and their effects will at least partly cancel one another out, because the electrons produced by the donor impurities recombine with the holes generated by the acceptor impurities. The ultimate character of the semiconductor material (n-type or p-type) depends on whether the number of electrons generated by the donors exceeds the number of holes generated by the acceptors or vice versa.

The action of nuclear radiation on a semiconductor material ultimately results in the creation of electron–hole pairs. The average energy \( \epsilon \) necessary to produce an electron–hole pair is found experimentally to be independent of the type and the energy of the incident radiation. The values of \( \epsilon \) are 3.62 eV in Si at 300 K and 3.76 eV in Si and 2.96 eV in Ge at 77 K (Table 2). The smallness of the average energy \( \epsilon \) compared with the average energy necessary to create an electron–ion pair in a gas (typically about 30 eV) represents an outstanding feature of semiconductor detectors and confers the superior energy resolution of these detectors. This follows from the increased (by about tenfold) number of charge carriers produced in the semiconductor as compared with the gas detector for the same energy deposited in the detector. The relative statistical fluctuation in the number of charge carriers per event becomes smaller as the total number is increased.

Once electrons and holes are formed in a semiconductor as a result of the action of nuclear radiation, these may recombine with one another, be trapped by impurities or imperfection centers or be collected at the electrodes of the detector, producing a useful signal. The charge carrier lifetime is measured as \( 10^{-2} - 10^{-4} \) s in the purest semiconductor materials available. On the other hand, the mean charge carrier lifetime from direct electron–hole recombination is estimated to be as high as about 1 s. Therefore, direct recombination is rather improbable, and the main factor determining the lifetimes of the charge carriers is the trapping effect. The trapped charge carrier is released back to the relevant band; however, the time delay (detrapping time) is often too long and, as a result, the charge carrier is lost to the charge collection process or is collected with significantly reduced efficiency. On the other hand, if the mean detrapping time is substantially shorter than the charge collection time, then the trap has no effect on the charge collection process. In modern semiconductor detectors, the maximum permissible concentration of trapping centers is of the order of \( 10^{10} \) cm\(^{-3} \), corresponding to approximately one
for every 10^{12} atoms of the host material. This results in high charge collection efficiency of the order of 0.999. The corresponding collection time is of the order of 10^{-7} s and carrier lifetime is of the order of 10^{-4}–10^{-3} s.

In summary, the physical properties required for a semiconductor detector material are as follows:

1. high specific electric resistivity to give low leakage current;
2. freedom from recombination and trapping of charge carriers to give efficient (preferably 100%) charge collection;
3. small width of the forbidden band to give a large number of electron–hole pairs;
4. high mobilities of both charge carriers to give a fast time response;
5. high atomic number Z to give a high photoelectric cross-section for γ- and X-ray spectrometry.

2.3.5 Basic Properties of the p–n Junctions

Virtually all semiconductor detectors exploit the remarkable properties of the junction created between two semiconductor materials with different types of conductivity. Such a p–n junction is formed if donor impurities are introduced into one side and acceptors into the opposite side of a single semiconductor crystal. When n- and p-type semiconductors are brought into contact, the electrons from the n-type material diffuse across the junction into the p-type material and the holes from the p-type material into the n-type material because there is a density gradient of the free charge carriers across the junction. Free electrons diffusing from the n-type into the p-type material combine there with the holes and disappear as a result of annihilation. Each free electron that disappears from the n-side of the junction leaves behind an immobile positively charged donor site. Similarly, the holes diffusing in the opposite direction annihilate with the free electrons in the n-type material, leaving behind immobile negatively charged acceptor sites. The accumulated space charge from the immobile donor and acceptor sites creates an electric field which eventually halts further diffusion. Since the region of the junction is depleted of mobile charge carriers, it is called the depletion region, or the space-charge region. If the concentrations of the donors on the n-side of the junction and acceptors on the p-side are approximately the same, the depletion region extends equally into both sides across the junction. However, this is not the case in semiconductor detector practice. Here an intentional strong asymmetry in the doping levels on each side of the junction is produced. In such a case, the depletion layer extends almost entirely into the low-level doping side of the junction.

The configuration just described is a junction diode. The width of the depletion region of such a diode is of the order of a 0.5 μm and the potential difference across the junction (the contact potential) amounts to a few tenths of a volt. An electric field across the junction sweeps the free charge carriers out of the depletion region. As a result, the carrier density concentration remaining in the depletion region is approximately eight orders of magnitude lower than typical carrier densities in the bulk material. Such a low concentration of free charge carriers in the depletion region means that the specific resistivity of this region is very high, as follows from Equation (6). As mentioned, high specific resistivity is one of the main properties required of the material for semiconductor detectors. The p–n junction diode can be used for the detection of nuclear radiation even with no external voltage applied because a nonzero electric field exists across the junction. If a charged particle enters the depletion region and creates electron–hole pairs, these will be swept out of the depletion region by the electric field towards the respective electrodes, and their flow forms a useful electronic pulse. However, the thickness of the depletion region in the unbiased junction diode is very small (<10^{-4} cm). As a result, the active volume of the detector is too small to be of any practical interest. For the same reason, the capacitance of an unbiased junction is high, resulting in very poor signal-to-noise properties of the detector. Therefore, unbiased junction detectors are not used as practical detectors of nuclear radiation.

The thickness of the depletion region of the junction diode is increased considerably by applying a reverse bias to the junction. The reverse bias causes both the holes in the p-side of the junction and the electrons in the n-side to move away from the junction. Consequently, the region of the uncompensated negative charge is spread into the p-side of the junction, and that of uncompensated positive charge is spread into the opposite n-side. Because practical detectors are operated with a very large reverse bias voltage (up to 3000 V) compared with the contact potential, the thickness of the depletion region is increased considerably, reaching more than 0.1 cm for Si diodes. As mentioned, the depletion region width is determined by the biasing voltage and also by the free carrier densities. Because the net charge must be zero, then we have Equation (10):

\[ N_A W_p = N_D W_n \]  

where \( N_A \) and \( N_D \) are the acceptor and donor concentrations in the corresponding sides of the p–n junction and \( W_p \) and \( W_n \) are the depths to which the space charge extends into the p- and n-sides of the junction. In semiconductor detector practice, the n-side of the junction is usually doped to a much greater extent than the p-side. Consequently, the depletion layer extends much further into the p-side than the n-side. In such a case, the width \( d \)
of the depletion layer is given by Equation (11):

\[ d \approx W_p = (2 \epsilon_o V \mu \rho_d)^{1/2} \] (11)

where \( \epsilon_o \) is the dielectric constant of the semiconductor, \( V \) is the reverse bias and \( \rho_d \) is the resistivity of the doped semiconductor. From Equation (11), it follows that the largest depletion layer is obtained when a semiconductor material of the highest resistivity is chosen and the largest possible reverse bias is applied to the junction. For the material to be of highest resistivity, it must have the highest purity possible. The largest reverse bias is limited by the maximum electric field occurring at the junction. It must be no more than \( 2 \times 10^4 \text{V cm}^{-1} \) under typical conditions. In addition, the reverse bias should not be increased above the point at which the detector becomes totally depleted.

The pulse magnitude observed in a semiconductor detector after the charge collection process is inversely proportional to the sum of the capacitance of the p–n junction and the input circuit. The signal-to-noise ratio of the system is improved if the capacitance of the junction decreases. Therefore, the largest possible reverse bias is preferable.

### 2.3.6 Charged-particle Detectors

In most cases, detectors for charged-particle spectrometry are reverse-biased diodes made with highly purified, single-crystal silicon. Silicon is chosen because its energy gap is large enough to ensure that the resistivity is sufficiently high even at room temperature. In addition, the low atomic number of Si is of no importance for charged particle detectors.

For detecting charged particles, a depletion layer must be located as close as possible to the surface of a detector, because the regions outside the depletion layer act as a dead layer for incoming charged particles. There are a number of technologies for manufacturing silicon detectors with surface junction construction. For example, the diffusion method of fabrication starts by diffusing a donor impurity, such as phosphorus, at a high temperature through the front face of a homogeneous crystal of p-type silicon. A p–n junction is formed at a distance of \( 0.1–1 \mu \text{m} \) from the surface of the crystal. Because the superficial n-type layer is heavily doped compared with the original p-type layer, the depletion layer extends primarily into the p-side of the junction. Therefore, the n-side of the junction represents a dead layer. The thickness of the dead layer should be determined experimentally to make possible accurate measurement of the energy of the incoming charged particles.

To avoid a large dead layer and the high temperature involved in the diffusion process, another type of surface junction detectors was developed, the surface barrier detector, which successfully replaced the diffusion detectors in many applications. Typically, a surface barrier detector is a diode made of an etched n-type silicon wafer with a very thin (40 \( \mu \text{g cm}^{-2} \)) layer of gold deposited by evaporation on the Si wafer. The gold layer forms a p-type rectifying contact on the diode. The other surface of the wafer is coated with a layer of 40 \( \mu \text{g cm}^{-2} \) of evaporated aluminum to produce good ohmic contact.

When a reverse bias is applied to the contacts (i.e., a negative voltage on the gold electrode), electrons from the vicinity of the gold electrode are swept away, creating a depletion region that forms a sensitive medium for detecting charged particles.

The entrance window (gold layer) of surface barrier detectors is so thin (\( \sim 0.02 \mu \text{m} \)) that it is transparent to the photons of visible light. To avoid a high noise level generated by normal light, surface barrier detectors are used in a lightproof environment, usually provided by the vacuum chamber required for most charged particle applications.

Another technique for producing the surface junction involves creating superficial layers of dopants by ion implantation. In this process, the ions of dopants from a small accelerator impinge on the surface of a crystal and penetrate a short distance into the crystal.

Surface junction detectors are available in a wide range of active areas from 7 to 2000 \( \text{mm}^2 \) and sensitive depths from 10 to 5000 \( \mu \text{m} \) and are therefore satisfactory for detecting many charged particles in a wide energy range.

From Equation (11) it follows that the width of the depletion layer is proportional to the applied voltage. According to the magnitude of the applied reverse-bias voltage, the detector is partially depleted, fully (totally) depleted or over-depleted. In the first case, the depth of the depletion region \( W \) is less than the physical thickness \( L \) of the detector. Partially depleted detectors are therefore sensitive to charged particles incident only on the junction surface of the detector.

Thin, totally depleted silicon detectors are widely used as transmission detectors for identifying charged particles based on their rate of energy loss \( \text{dE/dx} \). These are so-called \( \text{dE/dx} \) detectors. For this application, a very thin detector is chosen so that the particle emerges with minimum energy loss and can be further detected by another detector (telescope arrangement). The \( \text{dE/dx} \) detector should have dead layers as thin as possible on both the entrance and the exit sides of the detector. Planar, totally depleted, silicon surface barrier detectors are currently available in thicknesses down to 10 \( \mu \text{m} \).

As follows from Equation (11), the width of the depletion layer in the surface junction detector is determined by the resistivity (purity) of the starting silicon wafer and by the bias voltage applicable without
breakdown. The currently available purity of silicon is such that depletion thicknesses are limited to no more than a few millimeters. Greater thickness in silicon is obtained only with intrinsic material or through the use of material compensated by the lithium-drifted process.

Generally, all real semiconductor materials contain impurities of both n- and p-type. Because the electrons originating from donor impurities recombine with holes from acceptor atoms, it is obvious that a partial mutual compensation of impurities takes place. In such a case, the net concentration, \( N_D - N_A \), where \( N_D \) and \( N_A \) are the concentrations of donor and acceptor atoms, respectively, determines the type of semiconductor. If \( N_D > N_A \), then it is an n-type material, and vice versa. If, on the other hand, \( N_D = N_A \), then the semiconductor behaves like an intrinsic material. Such compensated materials are designated with the letter “i”.

The method of impurity compensation based on the process of lithium ion drifting was developed by Pell in 1960. The method is used effectively for compensating p-type silicon and germanium crystals after the crystals have been grown. The lithium drift method is based on the fact that lithium ions, being of small radius, are fast interstitial diffusant in both Ge and Si and act as donor impurities with very low ionization potential (0.033 eV in Si and 0.0043 eV in Ge). The mobility and therefore the coefficient of diffusion of Li ions are some \( 10^7 \) times greater than those of ordinary diffusants such as boron and phosphorus.

In both Si and Ge, the material with the highest available purity is of p-type. The process of lithium compensation starts by diffusing lithium, which acts as a donor, into the front surface of a p-type semiconductor. To increase lithium mobility, the temperature of the crystal is elevated to 500 °C. As a result of diffusion, an n-type region is created near the exposed surface of the crystal. The resulting p–n junction is then back-biased, and the positive lithium ions are slowly pulled further by the electric field into the p-region where their concentration increases and approaches the concentration of the p-type impurities in the original material. Simultaneously, the lithium donor concentration decreases in the n-region. The lithium ions, having high mobility, redistribute themselves under the influence of the local fields so that the total space charge in the drifted region tends towards zero at every point. Otherwise the local field would essentially reverse direction and would sweep the lithium ions back in the opposite direction. An equilibrium point is thus established in which the lithium ions go on to drift into the p-region, spreading themselves over the region so that the number of lithium donors compensates exactly for the acceptors of the original material. It has been shown by Pell that any deviation from exact compensation by the lithium ions during the drifting is unstable, and any instantaneous imbalance in lithium concentration is quickly eliminated by itself, thus restoring exact compensation. Using the lithium drifting process, thick compensated regions of up to 5–10 mm in Si and 10–15 mm in Ge are achieved. In this case, the drift process can take hundreds of hours. More detailed information about the lithium drift process is available.

Lithium ions have high mobility at room temperature, particularly in germanium. Therefore, to preserve the lithium concentration required for compensation, the Ge crystal must be cooled to liquid nitrogen temperature (77 K) immediately after the desired compensation is attained. In silicon, however, the lithium ion mobility is lower, so that lithium-drifted silicon detector can be temporarily stored at room temperature without cooling.

As mentioned, the problem of insufficiently thick depletion zone in semiconductor detectors was solved with the developing the lithium drifting process to obtain compensated material. Such silicon based detectors are called lithium-drifted silicon detectors, or Si(Li) detectors (pronounced “silly”). Junctions of the Si(Li) detectors are known as p–i–n junctions and their properties differ from the ordinary n–p junctions discussed earlier. Because, theoretically, no net charge exists in the compensated i-region, the resulting electric field is constant across the i-region, dropping sharply to zero at its boundaries. Therefore, the active volume of the detector is determined by the dimensions of the i-region.

The increased thickness of the compensated (active) zone of the Si(Li) detectors (5–10 mm) makes them suitable for the detection and spectroscopy of \( \beta \)-particles and low-energy X- and \( \gamma \)-rays. For the same reason, the bulk generated leakage current of Si(Li) detectors is a significant contributor to the noise. As a result, the detectors in these applications must be cooled to liquid nitrogen temperature. For this purpose they are mounted in a vacuum-tight cryostat incorporating a built-in sorption pump. A thin beryllium or Mylar window allows entry of the low-energy radiation into the detector. The cryostat is mounted on a liquid nitrogen Dewar vessel with a capacity of about 30 L. To diminish the contribution of the electronic noise in the energy resolution of Si(Li) detectors, they are supplied with a low-noise preamplifier incorporating a cooled first stage. Being low-energy \( \gamma \)-ray spectrometers, Si(Li) detectors are extensively used for the observation of the Mössbauer effect, where energies below 40 keV are of principal interest. As X-ray spectrometers they are widely used in source and tube-excited X-ray analysis for atmospheric, air and water pollution studies.

### 2.3.7 Germanium Detectors

Germanium detectors are mainly used in \( \gamma \)-ray spectroscopy because the atomic number of Ge (Z = 32)
is much higher than that of Si (Z = 14). The photoelectric probability, depending upon Z^2 to Z^4, is thus about 60 times greater in Ge than in Si. In general, much greater sensitive thicknesses are required to detect \( \gamma \)-rays than charged particles. Before the mid-1970s the required depletion depths were achieved only by counter doping p-type germanium crystals with lithium in the lithium-ion drifting process described above in connection with Si(Li) detectors. These lithium-compensated Ge-detectors are known as Ge(Li) (pronounced “jelly”) detectors.

To increase overall detector volume and thus detection efficiency, the Ge(Li) detectors are constructed in cylindrical or coaxial geometry. In true coaxial geometry, lithium diffuses on the outside of the p-type germanium crystal and drifts towards a central core under a strong electrical field, thus producing a cylindrical shell of high resistivity (intrinsic) material. A central core of insensitive p-type germanium extends along the entire length of the cylindrical crystal. In a closed-end coaxial configuration, lithium is also allowed to drift from the front face of the Ge crystal. As a result, the sensitive volume of the detector is increased even more. Coaxial Ge(Li) detectors are also constructed in a well configuration, in which the central insensitive core of the germanium cylinder is removed. Radioactive samples are then placed within the well, thus substantially increasing the counting efficiency. For lower \( \gamma \)-energies (up to several hundred kiloelectronvolts), Ge(Li) detectors are fabricated in a planar configuration, in which the electrical contacts are formed on the flat surfaces of a germanium disk a few centimeters thick.

To reduce the thermal charge carrier generation (electronic noise) to an acceptable level, Ge(Li) detectors must be cooled to liquid nitrogen temperature. The cooling of Ge(Li) detectors prevents lithium precipitation and thus protects from destruction. This is necessary because of the high mobility of lithium ions in germanium at room temperature. For this reason, Ge(Li) detectors must be kept at liquid nitrogen temperature at all times (both in operation and on storage). The germanium crystal and input stage of the preamplifier are installed in a vacuum chamber which is inserted in a liquid nitrogen container (Dewar), just as for Si(Li) detectors (Figure 4). At these temperatures, reverse leakage currents are very low, in the range 10^{-9}–10^{-12} A.^{(21)}

In the mid-1970s, advances in germanium purification technology produced high-purity germanium with an impurity level as low as 10^{10} atoms cm^{-3}. Detectors produced from this ultrapure Ge material are called high-purity germanium detectors, usually abbreviated as HPGe detectors. The outstanding feature of these detectors is that they do not have to be kept at liquid nitrogen temperatures at all times. HPGe detectors must be cooled only when a high voltage is applied. Between uses, these detectors can be held at room temperature.

Because HPGe and Ge(Li) detectors are virtually identical in construction and operation, their main performance characteristics are practically the same. On the other hand, because HPGe detectors are obviously much more convenient to operate than Ge(Li) detectors, they have almost completely replaced Ge(Li) detectors in contemporary \( \gamma \)-ray spectroscopy.

One of the main measures of the performance of nuclear detectors is their resolution. In general, resolution is the ability of a detector to separate two peaks close together in energy. Therefore, the narrower the peak, the better the resolution of the detector. Resolution is measured as the full width at half the maximum amplitude [full width at half-maximum (fwhm)]. Germanium detectors feature very high energy resolution capability compared with other types of radiation detectors (proportional counters or scintillation counters). Basically, the better energy resolution of Ge detectors is attributed to the small amount of energy required to generate a pair of charge carriers (electron–hole) in germanium. As a result, a greatly increased number of charge carriers is produced, forming the large output signal relative to that of other detectors. At about 3 eV per electron–hole pair (see Table 2), the
number of charge carriers produced in Ge is about one and two orders of magnitude higher than in gas and scintillation detectors, respectively. The energy resolution of Ge detectors expressed as fwhm in kiloelectronvolts is often specified at 5.9 keV ($^{55}$Fe), 122 keV ($^{57}$Co) and 1332 keV ($^{60}$Co). The representative fwhm values and the resultant improvement in energy resolution of Ge detectors over other types of radiation detectors are presented in Table 3.$^{[21]}$

The striking difference in energy resolution between a Ge detector and a $3 \times 3$ in NaI(Tl) scintillation detector is illustrated in Figure 5. The germanium detector used is a coaxial Ge(Li) detector with a 7.5% efficiency [compared with a standard $3 \times 3$ in NaI(Tl) crystal].

Efficiency is another important parameter of nuclear detectors. In general, the absolute, or total, efficiency of a γ-detector is defined as the ratio of the number of events registered by the detector to the number of γ-rays emitted by the source in all directions. The total efficiency depends on the probability of the interaction of a γ-ray with the detector sensitive medium and on the solid angle subtended by the detector. For historical reasons, a relative detection efficiency of germanium detectors is in common use in γ-ray spectrometry. It is defined at 1.33 MeV ($^{60}$Co) relative to the efficiency of a standard $3 \times 3$ in diam, 3 in long NaI(Tl) scintillator; each detector at 25 cm from a point $^{60}$Co source. Because the absolute efficiency of a standard $3 \times 3$ in NaI(Tl) crystal is well known ($1.2 \times 10^{-3}$), the relative detection efficiency is

involving moderate energies than any other detector. and consequently better resolution at low and moderate energies. The low-energy germanium detector affords lower noise preamplifier noise is a function of detector capacitance, detector is less than that of a planar device. Because is of less than full area, and thus the capacitance of the detector element is made of HPGe. Its cryostat window is made from beryllium for improved sensitivity to low-energy photons. The detector is used mainly in low-energy photon spectrometry in the energy range 3–200 keV. Curve 3 shows the absolute efficiency curve for a 10 cm² x 15 mm thick low-energy Ge detector; curve 4, 15% relative efficiency reverse-electrode Ge detector. The main performance parameters of Ge detectors, relating to low-level and environmental measurements, are efficiency (both at 25 cm and Marinelli efficiency), energy resolution, peak shape and peak-to-Compton ratio. The efficiency (at 25 cm) of Ge coaxial detectors is described in concise form in the previous section. The Marinelli efficiency is especially important in environmental applications involving measurements of weak activity. In such measurements, the environmental sample to be evaluated comprises large-volume materials, such as different fluids, soil or vegetation. In the early days of environmental studies, it was the practice to reduce the sample volume (e.g. by evaporation, ashing or leaching) in order to obtain a reproducible and optimized sample–detector geometry. To avoid the problems of efficient sample handling and the potential for sample loss, the use of small-volume detectors, such as the coaxial Ge detectors, was demonstrated to be more convenient and accurate. Curve 1, 10% relative efficiency reverse-electrode Ge detector. Curve 2, 200 mm² x 10 mm thick low-energy Ge planar detector; curve 3, 10 cm² x 15 mm thick low-energy Ge detector; curve 4, 15% relative efficiency reverse-electrode Ge detector. The main design feature of the detector is the 10 mm thick low-energy Ge planar detector; curve 3, 15 mm thick low-energy germanium γ-ray detector. Another feature of this detector is that it is about 10 times more resistant to radiation damage than conventional coaxial Ge detectors.

Typical absolute efficiency curves for various types of germanium detectors are presented in Figure 6. Curve 1 represents a 10% relative efficiency, coaxial, HPGe detector. It is used in general γ-spectroscopy for the energy range from 50 keV to more than 10 MeV. Curve 2 represents a 200 mm² x 10 mm thick planar detector. The detector element is made of HPGe. Its cryostat window is made from beryllium for improved sensitivity to low-energy photons. The detector is used mainly in low-energy photon spectrometry in the energy range 3–200 keV. Curve 3 shows the absolute efficiency curve for a 10 cm² x 15 mm thick, low-energy, germanium detector. This type of detector is fabricated with an ultrathin boron implanted p-contact on the front face and on the cylindrical wall. The n-contact, a lithium-diffused spot on the rear face, is of less than full area, and thus the capacitance of the detector is less than that of a planar device. Because preamplifier noise is a function of detector capacitance, the low-energy germanium detector affords lower noise and consequently better resolution at low and moderate energies than any other detector. For applications involving moderate γ-ray energies (5–500 keV), this type of detector outperforms an expensive large-volume coaxial detector. Curve 4 gives the absolute efficiency data for a 15% relative efficiency, reverse-electrode detector. The main design feature of the detector is the reversal of the electrodes from the configuration in a conventional coaxial detector. The p-type electrode (ion-implanted boron) is on the outside, and the n-type contact (diffused lithium) is on the inside of the Ge crystal. The ion-implanted outside contact is extremely thin compared with a lithium-diffused contact. In conjunction with a thin cryostat window, this results in an energy response down to 5 keV, giving this detector a dynamic range of 2000 : 1 (5 keV to 10 MeV). Another feature of this detector is that it is about 10 times more resistant to radiation damage than conventional coaxial Ge detectors.

High-resolution γ-ray spectroscopy is widely used in the evaluation of γ-emitting radioactive nuclides in various samples, such as soil, air, water and foodstuffs. In most cases, such an evaluation is based on the use of Ge detectors which have a number of benefits in analytical γ-spectroscopy. First, high-resolution, large and superlarge germanium γ-ray detectors are available with relative efficiencies up to 120%. Another benefit is the availability of low and ultralow γ-background cryostats and transplantable detector capsules which are easily switched from one cryostat to another without using any pumps, heater tapes or other accessories.

One purpose of radioactivity measurements at a low level (e.g. environmental samples) is to determine their contamination level and to limit the internal exposure of humans to radioactive species. The permitted levels of radioactivity are relatively low [e.g. following the Chernobyl nuclear accident, ad hoc limits were imposed on the content of radioactive Cs, typically 600 Bq kg⁻¹ in food and 370 Bq kg⁻¹ in milk]. Other examples of the low-level measurements of radionuclides include the monitoring of the environment and effluent discharge of nuclear power plants and evaluating the natural background. Because of diverse radionuclide content of the low-level samples, it has become standard practice to use high-resolution Ge detectors to resolve, identify and quantify the γ-emitting isotopes present.

The main performance parameters of Ge detectors, relating to low-level and environmental measurements, are efficiency (both at 25 cm and Marinelli efficiency), energy resolution, peak shape and peak-to-Compton ratio.

The efficiency (at 25 cm) of Ge coaxial detectors is described in concise form in the previous section. The Marinelli efficiency is especially important in environmental applications involving measurements of weak activity. In such measurements, the environmental sample to be evaluated comprises large-volume materials, such as different fluids, soil or vegetation. In the early days of environmental studies, it was the practice to reduce the sample volume (e.g. by evaporation, ashing or leaching) in order to obtain a reproducible and optimized sample–detector geometry. To avoid the problems
associated with the sample processing (cost and possible sample destruction), samples are now measured directly in Marinelli beakers without any preprocessing.

As mentioned above in connection with scintillation counting, the Marinelli (re-entrant) beaker allows the counting of an environmental sample in an optimum and reproducible geometry with minimum background by placing it as close to the sensitive detector volume as possible, a prerequisite for all low-level counting systems. This makes it necessary to specify the Marinelli beaker efficiency which differs, obviously, from the detector efficiency at 25 cm. Measurements show\(^{24}\) that although a large-diameter Ge detector may have a high relative efficiency for a given sensitive volume, when used with a Marinelli beaker geometry, it has an absolute full-energy peak efficiency lower than that of the lower relative efficiency detector. For these reasons, an American Nuclear Society (ANS)/Institute of Electrical and Electronic Engineers (IEEE) Standard has been introduced for the measuring detectors using the Marinelli beaker geometry. According to this standard, a detector is measured using a Marinelli beaker filled with 450 mL of a solid or liquid carrier containing a specified, uniformly dispersed, radioactive material. The solid carrier is preferable because it constitutes a safe and chemically inert sealed source. The filled beaker is designated a Marinelli Beaker Standard Source (MBSS).\(^{24}\) Employing the Marinelli beaker geometry, detectors are compared to provide meaningful measurements for different users and sites.

Energy resolution and good peak shape (symmetry) are very important parameters in the resolution of complex radionuclide mixtures in low-level counting. As mentioned, energy resolution is characterized by the fwhm at 1.33 MeV. Peak shape, the symmetry of the peak is measured by the full width at one-tenth maximum (fwm1)/fwhm ratio at 1.33 MeV. Ge detectors typically have fwm1/fwhm ratios of 1.9 or even less, which is very close to the ultimate value of 1.83 for the theoretical Gaussian peak.

The peak-to-Compton ratio is one of the most important measures of Ge detector performance. It characterizes a detector’s ability to distinguish low-energy peaks in the presence of high-energy sources. The peak-to-Compton ratio is obtained by dividing the height of the 1.33 MeV peak by the average Compton plateau between 1.040 and 1.096 MeV. Usually, higher peak-to-Compton values are achieved with better values of energy resolution. Ge detectors with good peak-to-Compton ratios are especially valuable in applications such as NAA and radiation waste analysis. In these applications, the isotopes of interest may have low activity compared with the activities of other isotopes in the sample, and therefore, may be hidden by the Compton plateau.

In the low-level counting applications, obviously, there is a need for Ge detectors with a low radioactive background, both external and internal. The main contributors to the external background are the cosmic rays, \(^{40}\)K from building structures and radon. This kind of background can be markedly reduced by appropriate shielding and by flushing the volume around the detector with a radon-free gas (boiled-off liquid nitrogen is often used). The main source of internal activity is the detector’s cryostat. It contains the primordial emitters \(^{238}\)U, \(^{232}\)Th, \(^{235}\)U and their progeny, which emit a mixed spectrum of \(\alpha\)-, \(\beta\)-, and \(\gamma\)-rays. In addition to the naturally occurring activities, there are also fission-related activities including \(^{137}\)Cs fallout and \(^{60}\)Co. This background includes both photopeaks and associated Compton continua, and it covers energy range from 46 to 2614 keV.

To achieve the ultimate in low-background counting, the main parts of the cryostat are made of special low background materials, such as magnesium (endcap), oxygen-free high conductivity (OFHC) copper (detector cup, cooling rod), activated charcoal (for cryosorption pumping) and low-cobalt stainless steel (cryostat flange).\(^{19}\) For the same reason, shielding of Ge detectors is essential to reduce external background radiation. A special low-background virgin lead with steel jacket is often used for this purpose. A 10-cm thickness of lead is sufficient for low-level counting applications covering the energy range from 0 to 2.6 MeV. Still greater thicknesses provide additional attenuation of \(\gamma\)-rays, but also increase the background from undesired cosmic-ray interaction with the lead shield. To reduce the unavoidable K X-ray of the lead (80 keV), a graded-Z shield is used, consisting of materials with decreasing atomic numbers (Z) approaching the detector to absorb the lead X-ray and emit a secondary X-ray of lower energy. Typical graded-Z shields are \(_{82}\text{Pb} (\sim 10 \text{ cm}, E_x = 80 \text{ keV}) \rightarrow _{48}\text{Cd} (\sim 0.5 \text{ mm}, E_x = 22 \text{ keV}) \rightarrow _{29}\text{Cu} (\sim 1.5 \text{ mm}, E_x = 3 \text{ keV})\).

For even lower-level measurements, active shielding methods, such as a Compton-suppression spectrometer,\(^{1,25}\) provide additional enhancement of the signal-to-background ratio and improve still further the minimum detectable activity (MDA). The Compton-suppression system is based on a well known and established fact that in the energy range between \(\sim 200\) keV and several MeV the most dominant interaction process between \(\gamma\)-photons and a Ge detector is Compton scattering, which gives rise to a powerful continuous (Compton) background in the energy spectrum, thus inevitably obscuring the low-activity photo-peaks to be sought in the same energy interval. Therefore, to improve the signal-to-background ratio and the MDA, the Compton continuum must be suppressed. This is done by means of anti-Compton shields surrounding a Ge detector and accompanying electronics. Such a system consisting of a
There is a need for prompt and economical in situ missioning and routine monitoring of nuclear facilities, of radionuclides deposited during emergencies, decommissioning of previously used nuclear sites, assessment of peak-to-Compton values as high as 940:1, depending on the detector chosen, have been reported. The NaI detector used for this purpose was a 9 × 9 in annulus, with a 3 × 3 in plug detector, the detector system being housed in a 35 × 35 × 75 cm lead shield, with 4-in thick walls, lined with 0.020-in Cd and 0.060-in Cu.

Indubitable benefits of using large, high-efficiency Ge detectors for the quantitative determination of environmental radionuclides have been discussed. It is pointed out that lower detection limits are obtained with higher-efficiency Ge detectors than with smaller ones. A single large detector results in a substantially higher sample throughput than multiple smaller detectors of the same total efficiency. This translates directly into cost-per-sample saving in a low-level counting laboratory.

In a wide range of applications, such as environmental restoration of previously used nuclear sites, assessment of radionuclides deposited during emergencies, decommissioning and routine monitoring of nuclear facilities, there is a need for prompt and economical in situ γ-spectroscopy. Such an in situ γ-spectrometer must be lightweight and portable, yet rugged enough to withstand a broad range of harsh environmental conditions. The best for this application is a portable, high-resolution HPGe detector mounted in a transplantable detector capsule attached to an all-attitude cryostat. A small-capacity Dewar vessel (e.g. 1.2 L) provides at least 12 h of continuous operating time. The measurements are made with the detector positioned 1 m above the ground. The methodology of these measurements was developed by members of the United States Department of Energy (USDOE) Environment Measurement Laboratory. This methodology is widely accepted for measurement of radionuclide-specific activity in the ground. It is based on empirically derived correction factors for detector orientation and for angular depth distribution of radioactive sources. By applying these correction factors to measured radionuclide intensity, an estimate of radioactivity per unit area or unit volume can be made.

Having unsurpassed energy resolution, HPGe detectors are widely used as photon spectrometers in NAA.

A well-resolved spectrum not only helps separate neighboring photopeaks but also aids in the detection of weak photons on the spectral continuum. This is particularly important for multielemental analysis when many elements in the sample matrix are irradiated by neutrons and emit up to several hundred prompt γ-rays simultaneously. As the HPGe detector is placed as close as possible to the neutron-irradiated sample (prompt activation analysis) to acquire the maximum counts, the detector is inevitably subject to neutron bombardment and excitation. In such a case, a typical prompt γ-ray spectrum of the HPGe detector itself under irradiation by neutrons should be used as a reference for the spectral background during prompt γ-counting. It should be pointed out that because the HPGe detector is subject to neutron irradiation during prompt γ-analysis, various degrees of damage to the detector can result from prolonged exposure to neutrons. For example, an exposure of an HPGe detector to a fast neutron fluence of 10^9 n cm^-2 is sufficient to risk the high-resolution performance and the detector may become unusable with exposure beyond 10^10 n cm^-2 owing to destruction of the crystal lattice.

Another possible application of HPGe detectors is in a high-sensitivity PIXE method in which X-ray emission is used for elemental analysis of all elements from boron to uranium bombarded by high-energy hydrogen or helium atoms with kinetic energies of a few MeV. HPGe detectors can be used up to and above 100 keV, which permits the detection of characteristic K X-rays for all elements. At lower X-ray energies, Si(Li) detectors must be used. Such detectors are sensitive to X-rays with energies between 1 and 30 keV. Above 30 keV the X-ray cross-section falls steeply and it is then not efficient to measure K X-rays from the heavier elements. Instead, L X-rays are used for the analysis of heavy elements, as they are more intense and are more efficiently detected in the Si(Li) detector.

The Si-based semiconductor detectors are used for charged-particle detection and spectroscopy. Ion-implanted, passivated, partially depleted Si detectors are widely used in α-spectroscopy of environmental samples for transuranics and to assess intake of these α-emitting elements. The light-tight option of the ion-implanted silicon detector with a protective polymer front-contact coating is employed for α- and β-continuous air monitoring in an adverse environment. Because α-particles are heavily attenuated even by air, α-spectroscopy with Si detectors must be performed with the samples in a vacuum chamber. For the same reason, extensive sample pretreatment is often required depending on the radionuclide involved and the medium in which it is contained.

Typical applications of environmentally rugged Si detectors include use in portable survey instrumentation, air monitors, α area monitors, personal α alarms/monitors,
alarm pocket dosimeters and others. Silicon detectors are used for α detection from radon and radon progeny in radon monitors and radon working level meters.

3 γ-RAY SPECTROSCOPY

3.1 Instrumentation for Nuclear Spectroscopy

Nuclear detectors provide a variety of information on detected radiation (energy, type of the radiation, timing data, etc.) in the form of electronic signals. To obtain this information, the signal must be processed by the appropriate nuclear electronics system. However, the subject of nuclear electronics is outside of the scope of this article and interested readers are referred to appropriate reference books.\(^\text{(1,32,33)}\) In what follows we present a short, qualitative description of the process of obtaining the most important characteristic of nuclear radiation, its energy distribution (energy spectrum).

A schematic diagram of the basic electronic equipment for measuring the energies of γ-rays is presented in Figure 7. A photon detector is represented as a capacitor in which charge carriers are generated by interaction of a nuclear particle within the detector. The high voltage provides the detector bias to collect the electric charge. As a result, a small (pulse) current flows, producing the pulse voltage drops across the bias resistor R. The voltage pulse produced enters into the preamplifier isolated from the high voltage by the capacitor C. In general, the preamplifier serves for the initial amplification of the detector output signal. The preamplifier is usually located as close to the detector as possible to reduce excessive cable capacitance, which lowers the pulse height and degrades the rise time of the pulse. Also, such positioning amplifies the signal before it enters a long cable leading to the main amplifier. Because the capacitance of most solid-state detectors depends upon the high-voltage bias, a charge-sensitive preamplifier should be used. The voltage pulse produced at the output of the preamplifier is then be proportional to the collected charge and independent of detector capacitance.

The main amplifier shapes the pulse for further processing and amplifies the pulse from the preamplifier to make it compatible with the input range of the spectrum analyzer. In energy spectroscopy, the pulse-height information is of primary importance. Therefore, very strict proportionality between the input and output amplitudes of the main amplifier must be maintained. Generally, the pulse at the output of a preamplifier has a fast rise time, ranging from a few nanoseconds up to a few microseconds, and a slow decay time of about 50 µs. The amplitude of this pulse is proportional to the energy of the radiation to be measured. Therefore, the long decay time of the preamplifier output pulse may cause the distortion of the energy information of the second pulse, if it rides on the tail of the first pulse. This is the so-called pile-up effect.

Another shortcoming of tailed pulses is their bad signal-to-noise ratio;\(^\text{(34)}\) in fact, it would be more advantageous to have a Gaussian or triangular pulse shape. For this purpose, RC clipping is used, in which the tailed pulse is differentiated to remove the slowly varying tail. Subsequent integration reduces the noise. The resulting pulse is much shorter and has a near-Gaussian shape with improved signal-to-noise characteristics and count rate capabilities.

Specially shaped pulses from the output of the main amplifier are directed into the pulse-height analysis system. This may consist of either a single-channel analyzer (SCA) and a counter or a MCA (see Figure 7).

The SCA is an electronic device which analyzes and sorts incoming pulses according to their amplitudes. It has both lower-level and upper-level discriminators, which define a certain amplitude range in the main amplifier output. The span between the lower-level and upper-level discriminator thresholds is called the SCA window. Only pulses with amplitudes falling within the SCA window result in a standard logic output pulse from the SCA. Pulses with amplitudes below the lower level or greater than the upper-level setting are rejected and do not produce output pulses. With the detector output proportional to energy, the SCA is used to obtain energy spectra of the incident radiation. For this purpose, the lower level and upper level of the SCA are set to give a fixed, narrow window, and full sweeping of the window is performed across the pulse-height range under consideration. The number of pulses counted by scaler (counter) at each step and normalized per unit time is then presented as a histogram of the energy spectrum. However, full data collection and processing by a SCA are tedious and time-consuming. Automatic and fast acquisition of energy spectra data is achieved by the MCA. An MCA can be considered as a succession of SCAs with the same window-width settings. All windows are arranged sequentially in order of increasing energy. Thus, by representing the number of counts of each SCA versus the mean energy of the corresponding window, a

![Figure 7 Schematic diagram of electronics for energy measurements of a nuclear radiation.](image-url)
histogram of a number of counts versus energy, i.e. an
energy spectrum, is obtained.

In an actual MCA, the succession of SCAs is replaced
by a special device called an analog-to-digital converter
(ADC). This is the core of an MCA. The ADC measures
and digitizes the height of each pulse to be analyzed
and determines to which pulse-height window this pulse
corresponds. The MCA then takes this window number
and adds to a memory channel whose address corresponds
to the digitized value. In this way all incoming pulses are
sorted according to pulse heights represented by channels.
The content of each channel is stored in the memory. The
total number of channels into which the voltage range of
input pulses (0–10 V) is digitized is called the conversion
gain. This gain determines the resolution of the MCA and
ranges from 64 up to 16 K in contemporary MCAs.

An input pulse is delayed while checking is performed
to see if it is within the selected SCA range. If it is, the
input pulse is passed to the ADC. The ADC digitizes
its amplitude, generating a number proportional to the
pulse voltage. This number represents an address in the
memory to which one count is added. The display reads
the memory many times per second, producing a point
plot of memory contents versus memory locations, which
is equivalent to the number of pulses versus voltage, i.e.
energy spectrum.

MCAs provide a number of possibilities for manipulation
of a spectrum display and the data stored in memory.
This includes expanding or contracting, linear or loga-
rithmic display modes and calculational capabilities, such
as energy calibration, peak searching, area extraction,
background subtraction and many others.

3.2 Energy Measurements

There are three principal kinds of interactions of photons
with matter, the photoelectric effect, Compton scattering
and pair production. All three processes are strongly
dependent on the energy of the photon and the atomic
number Z of the material. In the photoelectric process,
a photon is absorbed by an atom and, as a result of
the absorption, a photoelectron is emitted. Its energy
is equal to photon energy minus the binding energy.
The photoelectric cross-section increases very strongly
with increase in Z of the material and decreases with
increase in photon energy. The photoelectron produces
the electron–hole pairs in the sensitive medium of the
detector, resulting in the output pulse. Electrons have a
short range in the crystal and therefore all of their energy
is deposited in the detector.

At higher photon energies, the dominant interaction is
Compton scattering. In the Compton process, the photon
interacts with what might be termed a free electron,
losing part of its energy to the electron and scattering to a
different direction. Because the energy of the original
photon is shared between two particles in Compton
scattering (the recoil electron and the scattered photon),
there is a continuous distribution of pulse amplitudes
of Compton electrons up to some maximum pulse height.
This maximum pulse height produces the Compton edge,
which is the maximum energy that can be imparted to an
electron in head-on collision. It is given by Equation (12):

\[ E_{e}^{\text{max}} = \frac{E_0}{1 + m_0c^2/2E_0} \]  

where \( E_{e}^{\text{max}} \) is the maximum electron energy, \( E_0 \) is the
incident photon energy, \( m_0 \) is the electron rest mass and \( c \)
is the velocity of light.\(^{(1)}\)

Pair production is the third important process of photon
interaction with matter. The photon enters the detector
and creates an electron–positron pair in the field of a
nucleus. From the law of conservation of mass and energy,
it follows that the initial photon must have an energy of at
least 1.022 MeV (=2m_0c^2) because this is the exact energy
necessary to create both an electron and a positron.

To show the relative probability of each of the three
types of interactions, in Figure 8 graphs of the
absorption cross-section for germanium are presented.
As shown, at low energies up to about 200 keV, the
photoelectric effect is dominant. Compton scattering
becomes more important near 200 keV. Above 1.02 MeV,
pair production increases in probability.

All three processes determine the response of a solid-
state detector to monenergetic \( \gamma \)-rays. The relative
importance of these processes for detector response lies
in the proportion of the incident \( \gamma \)-ray energy deposited
in the detector-sensitive medium. A typically idealized
response of a solid-state detector to monenergetic \( \gamma \)-rays
is presented in Figure 9.

The full-energy peak, or photopeak, results from the \( \gamma \)-
photon losing all of its energy by photoelectric absorption
or Compton scattering followed by photoelectric absorp-
tion in the detector. Compton scattering causes only
a fraction of the energy of the initial photon to be
deposited in the crystal because the scattered photon
can escape from the crystal without further interaction.
This process contributes to the energy response of the
detector in the so-called Compton continuum, ranging
from zero up to a maximum determined by the Compton
edge (Equation 12). If the energy of an incident photon
is above 1.022 MeV, pair production occurs. The positron
produced slows in the crystal to an energy close to
that of the atomic electron and annihilates, producing
two 0.511-MeV photons. Each of these photons escapes
from the detector totally or deposits only part of its
energy by Compton scattering. If one of these photons
escapes totally, the total energy absorbed is 0.511-MeV
less than the original incident photon energy. If both
annihilation photons escape totally, the total deposited energy is 1.022 MeV less than the original photon energy. Therefore, in the measured spectrum, in addition to the full-energy peak, there are two additional peaks, a single-escape peak at energy \( (E_f - 0.511) \text{ MeV} \) and a double-escape peak at energy \( (E_f - 2 \times 0.511) \text{ MeV} \) (Figure 9). The single- and double-escape peaks appear only if the incident photon energy is above 1.022 MeV.

The detector response presented in Figure 9 is idealized, because it does not take into account broadening of all peaks by the final resolution of the detector and the effect of multiple Compton scattering.

Figure 10 represents a real spectrum of monoenergetic \( \gamma \)-photons from \(^{137}\text{Cs} \) in a 5 \( \times \) 5 cm \( (2 \times 2 \text{ in}) \) NaI(Tl) scintillator. The photopeak at 0.662 MeV is clearly separated from the Compton edge (0.478 MeV). Multiple Compton scattering fills the gap between the Compton edge and the photopeak, forming continuity in the spectrum from zero to the photopeak energy. The final resolution of the detector broadens the photopeak and rounds off the Compton edge and backscatter peak at 0.184 MeV. Backscatter occurs when photons from the source produce Compton interactions in the materials surrounding the detector, e.g. Pb shielding. Backscattered photons are then detected through photoelectric absorption when they enter the detector. The energy of the backscatter peak is \( E_{0}/(1 + 2E_{0}/m_0c^2) \).

To obtain information on physicochemical forms of radionuclides in the environment, speciation techniques should be applied in situ, at-site or in laboratories shortly after sample collection. Among speciation techniques for radionuclides in waters, combined in situ ultrafiltration and exchange chromatography are most promising as radionuclides species are fractionated with respect to nominal molecular mass and change properties simultaneously. However, the fractionation and characterization of chemically well-defined low molecular mass (LMM) species in waters is still a challenge. Surface analytical techniques (e.g. electron microscopy) are useful for characterizing colloids and particles with respect to structure and radionuclide distribution. Recent development within synchrotron-based X-ray microbeam techniques allows detailed information of crystallographic structure (micro-X-ray diffraction (μ-XRD)), oxidation states (micro-X-ray absorption near-edge spectroscopy (μ-XANES)) and volume distribution (μ-XANES tomography) of particle-associated radionuclides on the micrometer scale. Information on radionuclides reversibly or irreversibly associated with solid surfaces (binding mechanisms) is attained by different extraction techniques, while dynamic tracer experiments can provide information on the kinetics involved.

1 INTRODUCTION

To assess short- and long-term consequences of naturally occurring and artificially produced radionuclides released to the environment, information on the distribution of radionuclide species influencing mobility and biological uptake is essential (Figure 1). Radionuclides may be present in different physicochemical forms (i.e. radionuclide species) varying in size (nominal molecular mass), structure and morphology, density, oxidation states and charge properties. LMM species are believed to be mobile and potentially bioavailable, while high molecular mass (HMM) species, such as colloids, pseudocolloids and particles are inert. Thus, development within speciation of radionuclides, i.e. analytical techniques applicable for fractionation, identification and characterization of radionuclide species in waters, soils and sediments, is essential for improving the prediction power of assessment models.

The distribution of species will depend on the source in question, release scenarios, course of events, dispersion processes and physicochemical conditions (e.g. pH, redox, microbial activities) at the deposition site. Following accident releases from nuclear installations, the physicochemical forms of radionuclides will be completely different to those released during normal operations. Hence the distribution of radionuclide species and key properties of specific species, e.g. radioactive particles, may reflect the source of release. After deposition, however, the original distribution of radionuclide species will change with time owing to interactions with natural components (e.g. humic substances, clay minerals) and weathering.
2 THEORY AND OPERATING PRINCIPLES

The distribution of radionuclide species in natural waters and in soils and sediments will depend on source term characteristics and trace chemistry phenomena taking place in dilute aquatic solutions, in addition to interactions occurring in heterogeneous soil–water and sediment–water systems at deposition sites.

2.1 Source Term Characteristics Including Physicochemical Forms

The major sources of artificial radionuclides in the environment\(^1\) are fallout from 522 atmospheric nuclear weapon tests and authorized or accident releases from the nuclear fuel cycle, especially reprocessing plants (e.g. Sellafield in the UK, La Hague in France and Mayak PA in Russia) and nuclear reactors (e.g. Chernobyl in Ukraine). Releases from satellite, aircraft and submarine accidents and also dumping of radioactive waste at sea have a local impact only.\(^2\) Among artificially produced radionuclides released to the environment, \(^{137}\)Cs, \(^{90}\)Sr and Pu isotopes are of major radiological concern, even though several other long-lived radionuclides (\(^{99}\)Tc, \(^{129}\)I, \(^{237}\)Np, \(^{3}\)H, \(^{14}\)C, etc.) are also released from nuclear installations. For dose-assessments, however, the contribution from naturally occurring nuclides can be substantially higher than from artificially produced nuclides\(^\text{1-3}\) in particular from U and Th decay products such as Po and Pb isotopes in alum sheet areas. In groundwaters, natural radionuclide species (LMM species, colloids, particles) released from rocks due to dissolution and desorption processes, erosion and atomic recoil from radioactive decay dominate. In surface waters, the concentrations of cosmogenic radionuclides (e.g. \(^3\)H, \(^7\)Be, \(^{10}\)Be, \(^{14}\)C), aerosol-associated radon decay products (e.g. \(^{210}\)Po, \(^{210}\)Pb) and artificially produced radionuclides (LMM species, colloids, particles) in fallout or from effluents show spatial and temporal variations, depending on sources and distance from sources, wind direction and water pathways, climate and weather conditions. Sources and processes influencing the speciation of natural occurring radionuclides have been thoroughly discussed previously.\(^\text{3-4}\)

Source term characteristics (i.e. activity concentration of individual radionuclides, activity ratios and physiochemical forms of radionuclides) serve as input to dispersion, transport, ecosystem transfer and dose-assessment models. Usually source term information is restricted to inventory estimates (total radioactivity, becquerels), or to activity concentrations of different radionuclides in air (becquerels per cubic meter) or on the ground (becquerels per square meter), while information on the physiochemical forms (e.g. ions, complexes, colloids, particles) is scarce. The distribution of physiochemical forms varying in size (nominal molecular mass distribution), structure and morphology, density, oxidation states and charge properties will depend on the particular source and release scenario, course of events, distance.

Figure 1 Assessment models depend on source terms (physicochemical forms), mobility and bioavailability of released radionuclides.

Processes, LMM species may be irreversibly sorbed on solids, whereas radionuclides associated with radioactive particles can mobilize with time owing to weathering. Therefore, experimental information on transformation processes and kinetics changing the original distribution of mobile and bioavailable species radionuclide species over time is also required if uncertainties associated with transport models, ecosystem transfer models and dose-assessment models are to be reduced.

Similarly to trace element speciation, the analytical strategy includes in situ, at-site or shortly after sampling-fractionation techniques to obtain information on the actual distribution of radionuclide species. For radionuclides present in low concentrations in water, in situ or at-site size-fractionation techniques applicable for large volumes provide information on the distribution of radionuclide species according to size classes, i.e. LMM species, colloids, pseudocolloids and particles. When interfaced with charge fractionation techniques, information on the size distribution of neutral and charged LMM radionuclide species can be obtained simultaneously. For radionuclides in soils and sediments, the mobile fraction includes LMM species in soil waters and also species reversibly sorbed on solid-phases. To distinguish between species reversibly and irreversibly associated in soils or sediments, extraction techniques are useful, whereas for solid radioactive particles sensitive surface analytical techniques can be applied. Information on radionuclide species, interactions and kinetics can also be obtained from dynamic model experiments by adding chemically well-defined radioactive tracer species to soil–water and sediment–water systems, preferably in the field. Although radionuclide speciation is still an analytical challenge within radioecology, major progress has been achieved in recent years, as experience from trace element speciation has been adopted.
from the source, dispersion and deposition conditions. During normal operations, effluents from reprocessing plants (e.g. Sellafield, UK; La Hague, France; Mayak PA, Russia) and nuclear reactors (e.g. Sweden) contain LMM species, colloids and particles, while volatiles are released to the atmosphere. Condensed particles may form if volatiles are condensed on available aerosol surfaces, during the release and during transport.

At nuclear test sites (e.g. Marshall Islands, Maralinga and Emu sites in Australia; Mururoa, French Polynesia), radioactivity radionuclides (e.g. 95Zr, 144Ce) indicates release of polynuclear species, during the release and during transport. Condensed particles may contain LMM species, colloids and particles, while volatiles may also be depleted to variable degrees in volatile radionuclides (e.g. 137Cs and 90Sr). The presence of refractory radionuclides (e.g. 95Zr, 144Ce) indicates release of fuel particles, and the activity ratios may reflect fuel burnup. However, fuel particles have also been released to the atmosphere at low-temperature (e.g. Windscale piles in the early 1950s). Radioanalytical work, carried out in connection with nuclear weapon tests, nuclear accidents and releases from nuclear installation during normal operations, has highlighted the radioanalytical challenges associated in particular with radioactive particles or aggregates and the need to characterize them in terms of their radionuclide composition, structural and morphological properties and physicochemical forms, especially oxidation states of matrix elements. Since a significant part of the activity can be carried by radioactive particles, fractionation techniques should be performed preferentially in the field to differentiate between radionuclide species released from a source.

### 2.2 Dilute Solution Chemistry

In dilute aquatic systems, trace chemistry phenomena which are negligible at macro-concentrations become significant; the reaction rates may decrease as the probability of effective collisions decreases and reaction mechanisms may change as the chemistry at phase boundaries or the chemistry of colloidal systems becomes predominant. The concentration of most radionuclides in natural waters is very low and the borders between categories of radionuclide species ranging from simple ions, molecules or complexes, through hydrolysis products and polymers, colloids and pseudocolloids, to species sorbed or incorporated in suspended inorganic or organic particles and organisms are difficult to establish as there is continual transition between species (Figure 2). As natural waters are dynamic systems, the distribution of species exhibits spatial and temporal variations due to transformation processes. Owing to sorption on available surfaces, complexation with naturally occurring ligands, polymerization and aggregation of colloids, LMM forms are transformed to HMM forms, while desorption, displacement, dissolution and dispersion processes may mobilize LMM forms to the aquatic phase. Thus,

![Figure 2](image-url)

**Figure 2** Size classes for the different physicochemical forms of radionuclides in aquatic systems. Transformation processes changing the distribution of species are indicated.
fractionation should take place in situ, at-site or shortly after sampling as storage of water samples prior to fractionation may influence the actual distribution of radionuclide species.

Information on trace chemistry phenomena, including physicochemical forms of radionuclides, interactions and kinetics of importance for mobility and bioavailability, should be based on experimental data from natural systems. The lack of sensitive, species-specific detectors necessitates the use of fractionation techniques similar to those used for trace element speciation purposes. As for trace elements, the distribution of radionuclide species is expected to vary substantially, depending on macrochemical conditions (pH, Eh, ionic strength, temperature) and also on the quality and quantity of interacting components (e.g. humic substances, Fe, Al, Mn).

2.3 Particles, Colloids and Complexes

Owing to weathering, U, Th and decay products such as 210Po and 210Pb may be associated with particulate or colloidal material in aquatic systems. Following the diffusion of radon into the atmosphere, decay products such as 210Po and 210Pb may also associate with aerosol particles and return to the terrestrial environment via wet and dry deposition. Following nuclear weapon tests or nuclear accident releases, a major fraction of radionuclides is associated with particles or aggregates (≥0.45 μm). As observed close to the Chernobyl reactor, more than 90% of radionuclides deposited were associated with particles in the micrometers to millimeters range, and deposition densities up to 10^5 particles m^-2 have been reported. Smaller radioactive particles (micrometer range) were also observed up to 2000 km from the site. After deposition, weathering of radioactive particles occurs and associated radionuclides are mobilized with time. Information on the particle composition (e.g. UO_2 fuel), structural changes (e.g. oxidation of UO_2 to U_2O_5 during release or after deposition) and chemical conditions (pH, redox, microbial activity) at the deposition site is essential to assess weathering rates and the subsequent mobilization of associated radionuclides. Based on Chernobyl samples collected over a 10-year period, the particle weathering constant was found to vary from 0.04 to 0.42 yr^-1. A low weathering constant was associated with fuel particles released during the initial explosion and deposited to the west of the reactor, whereas a high weathering constant was associated with oxidized U_2O_5 particles released during the fire and deposited to the north of the site. Within the 30-km zone, the weathering rate (bequerels released per unit time) of fuel particles is reported to be slower than the interaction (strong fixation) rate for 137Cs in soils. For 90Sr in soils, however, the rate of interaction (weak association) is significantly lower than the weathering rate. As the potential transfer of released radionuclides within the ecosystem over time will depend on ratios between particle weathering rates and rates of interaction (strong fixation or weak association) of mobilized radionuclides, the mobility and biological uptake of 90Sr are expected to increase with time as weathering proceeds.

Colloidal forms of radionuclides (Figure 2) may be released from a source (e.g. effluents) or radionuclides may form colloids (1–10 nm) in aquatic systems. Furthermore, pseudocolloids are formed by the interaction of reactive radionuclides with surfaces of natural colloidal or pseudocolloidal material (diameter 1–450 nm), being important transporting agents for trace elements and radionuclides in natural water systems, for instance in aerial transport, rain water, soil–water, groundwater, runoff and river water, lake water and seawater. Chernobyl-contaminated runoff to a mountain lake was characterized by 137Cs associated with colloidal material, while 90Sr was present in LMM forms. Budget calculations also showed that colloidal 137Cs was retained in the lake, whereas 90Sr as mobile LMM species was transported through the lake and downstream.

The presence of colloidal material is favored under low-temperature conditions, and the surfaces of colloids in natural waters are usually negatively charged, partly due to organic coatings. Changes in chemical conditions, for instance, in mixing zones (fresh waters, estuaries) where waters of different qualities mix may significantly influence the stability of colloids (relationship between attractive van der Waals forces and repulsive Coulomb forces) and aggregation and particle growth occur until sedimentation takes place. Furthermore, polymerization of scavenging elements such as aluminum may occur in mixing zones. Hence trace amounts of charged radionuclide species present in unstable mixing zones such as estuaries may be affected by processes controlled by the macrochemistry of stable elements.

The use of organic ligands (e.g. ethylenediaminetetraacetate, diethylenetriaminepentaacetate, nitrilotriacetate, citrate) for separating radionuclide complexes is well known within radiochemistry. Thus, tables with laboratory-based stability constants for a large variety of radionuclide organic complexes have been developed over decades, often based on radioactive tracers and synthetic organic standards. The interaction with nonpolymeric and noncolloidal organic ligands may take place via carboxylic group interactions (organic salt), covalent bonds with carbon atoms or via electron-donating atoms (O, N, S, etc. coordination complexes) or by overlap of π-electron orbitals (π-complexes). Several mechanisms may be involved simultaneously. Radionuclides
can be released to the environment as stable complexes or chelates\(^5\) or especially for multivalent radionuclides (e.g. actinides such as Th, U, Np, Pu, Am) may form complexes owing to interactions with naturally occurring organic ligands.\(^{35,38}\) The mobility is usually increased as radionuclides reversibly associated with surfaces of solids may desorb upon the complex formation, and the sorption of organic complexes to negatively charged surfaces is usually low (low distribution coefficient, \(K_d\)). Forming lipophilic organic complexes, the transfer through biological membranes is also usually enhanced (i.e. increased bioavailability). Especially in groundwaters, inorganic complexes, e.g. carbonato or mixed hydroxo–carbonato complexes, play an important role in transport of radionuclides such as \(^{210}\)Pb and actinides.\(^{3,39}\)

Inorganic ligands forming stable complexes or chelates are also frequently applied for the separation of specific radionuclides. A well-known ligand is hexacyanoferrate, used for fractionation of positively charged Cs isotopes from large volumes of waters or used as a countermeasure when administered to animals to reduce the activity concentration of Cs isotopes in animal products.\(^{40}\) Although information on complex or chelate formation of radionuclides with naturally occurring ligands, especially organic substances such as humic or fulvic substances, has been improved during recent years, the development of fractionation techniques differentiating between radionuclides associated with organic complexing ligands, organic polymers and organic colloids still represents an analytical challenge.

### 2.4 Association with Solid Phases

Processes occurring in soil–water or sediment–water systems influencing the mobility of trace metals and radionuclides and the transfer to vegetation via root uptake have been intensively studied, especially in cultivated areas, over decades. Several concepts and models have also been developed during recent years.\(^{41–43}\) Except for sieving techniques and grain-size analysis, however, speciation studies in heterogeneous soil–water and sediment–water systems are still suffering from a lack of well-defined methods.

The term “mobile species” in soils and sediments refers to LMM species, e.g. ions or complexes soluble in soil water (≤0.45 μm) and species reversibly associated with solid surfaces (Figure 3). Thus, a fraction of mobile species may be available for active biological uptake. The term “inert species” includes radioactive colloids, pseudocolloids and particles deposited in soils or sediments, as well as radionuclides irreversibly bound to or incorporated into mineral lattices. The systems are dynamic; equilibrium may establish relatively rapidly between LMM forms in soil solutions and species reversibly associated with surfaces of solids, but slowly for species penetrating diffuse double layers of colloids and particles into mineral lattices.\(^{44}\) Thus, equilibrium within systems may not have been established when samples are collected.

The transfer of radionuclides in soil–water or sediment–water systems is frequently modeled using distribution coefficients, \(K_d\) (Bq kg\(^{-1}\) soil or sediment per Bq L\(^{-1}\) or Bq m\(^{-3}\) water). Hence, the models refer to equilibrated systems. Information on \(K_d\) is usually based on measurements of total concentrations of radionuclides in contaminated soils or sediments and in waters (e.g. pore water, lake or seawater). Large variations are seen, however, for reported \(K_d\) values in the literature,\(^{45}\) partly owing to the fact that equilibrium has not been established. As the system is dynamic, the distribution of radionuclides between solid and solutions should be described as a time-dependent function. Time-dependent functions are also relevant if radioactive particles are present in soils or sediments (Figure 3). In this case, the apparent \(K_d\) will be very high, indicating that soils or sediment will act as an efficient sink. As weathering occurs and radionuclides such as \(^{90}\)Sr are mobilized over time, however, the distribution of nuclides between solid and solution is reduced over time and the observed \(K_d\) cannot be considered to be constant.

To improve the resolution in \(K_d\), water can be fractionated with respect to LMM species (section 4), and extraction techniques can be utilized to distinguish between reversibly and irreversibly associated radionuclides in soils and sediments (section 5). Thus, observed \(K_d\) can be differentiated between \(K_{d,\text{reversible}}\) and \(K_{d,\text{irreversible}}\) for modeling purposes. Alternatively, laboratory experiments where soil or sediment samples are incubated for
a certain time period with synthetic solutions to which a chemically well-defined tracer has been added have been applied.\textsuperscript{[41]} During recent years, incubation techniques have been further developed to improve prediction models based on $K_d$ values (section 6).

A major analytical problem is the lack of appropriate in situ fractionation techniques to study interactions of radionuclides in soil–water or sediment–water systems. However, techniques can be applied at-site or in the laboratory shortly after sampling, provided that the systems are not manipulated prior to fractionation (e.g. dried or homogenized samples).

2.5 Bioavailability

Within radioecology, the transfer from soils, sediments or water to vegetation, animals or fish is usually described by a transfer coefficient (TC) (Bq kg\textsuperscript{-1} vegetation per Bq m\textsuperscript{-2} soil), transfer factor (TF) (Bq kg\textsuperscript{-1} vegetation per Bq kg\textsuperscript{-1} soil) or concentration factor (CF) (Bq kg\textsuperscript{-1} animal per Bq kg\textsuperscript{-1} fodder or Bq kg\textsuperscript{-1} fish per Bq m\textsuperscript{-2} water). The coefficients or factors are based on total activity concentrations\textsuperscript{[44,45]} owing to the lack of information on bioavailable radionuclide species present. However, TC, TF and CF show large seasonal variations and the analytical data reported in the literature are scattered. Thus, uncertainties associated with these variables contribute significantly to the overall uncertainties in predicting consequence assessments. The relationship between trace metals or radionuclide species and biological uptake in aquatic organisms has been thoroughly discussed by Simkiss and Taylor\textsuperscript{[46]} and Fisher and Reinfelder.\textsuperscript{[47]} LMM forms, often referred to as “free ions” or “labile” species in the literature, such as cations, hydrated ions, charged or neutral complexes and organometallic compounds including lipophilic complexes, are potentially able to penetrate biological membranes. Most data on the bioavailability of radionuclides are, however, obtained from model biotest experiments (section 6).

Radionuclides associated with colloids and particles are considered inert and the active biological uptake in plants and animals should be low. Therefore, in areas heavily contaminated with radioactive particles, as seen close to the accidental site in Chernobyl, TC, TF and CF reflecting the transfer to biological systems (e.g. vegetation, animals, fish) should be low. Field experiments performed within the Chernobyl 30-km zone demonstrated also that the “relative biological availability” of \textsuperscript{137}Cs from soil to grass was low compared with that of an added ionic Cs tracer.\textsuperscript{[48]} Furthermore, several studies have confirmed that particle weathering and the subsequent increases in \textsuperscript{90}Sr mobility are accompanied by increases in soil-to-plant TFs in the 30-km zone,\textsuperscript{[27]} and that the transfer increases with distance from the source. As an alternative to TC or TF, a mobility factor (MF)\textsuperscript{[49]} can be calculated according to Equation (1):

$$MF = \frac{\text{mobile species (Bq m}^{-2}) \times 100(\%)}{\text{total deposition (Bq m}^{-2})}$$

where mobile species include the species reversibly associated with solids in soil (or sediment) and species taken up by vegetation from the same site (becquerels per square meter). Thus, the pool of mobile species in soils is assumed to act as a reservoir for root uptake. By including mobile species taken up by vegetation, MF is less sensitive to seasonal variations due to vegetation growth. For particle-contaminated soils (Chernobyl), the mobile fraction, and hence, MF, are small. For samples collected in Ukraine, Belarus and Norway, the calculated MF also demonstrated low mobility of \textsuperscript{90}Sr close to the reactor, whilst MF increased with increasing distance from the reactor.\textsuperscript{[49,50]}

Following the Chernobyl accident, numerous animal feeding experiments with contaminated fodder have been performed\textsuperscript{[40]} and the quality of data with respect to uptake, accumulation, distribution of radionuclides in biological compartments, excretion and CF values has been significantly improved. In most models, the animal digestion of fodder contaminated with radioactive particles is not taken into account, i.e. CF is expected to be low. However, fuel particles retained as a point source in the gastrointestinal tract may be trapped much longer than previously anticipated and uptake may occur from digestion.\textsuperscript{[51]} In areas contaminated with radioactive particles, the influence on radionuclide speciation from microorganisms due to bioerosion,\textsuperscript{[52]} especially from certain fungi in soils and from benthic organisms in sediments, may be significant. Furthermore, retention of colloids or particles in filtering organisms may represent an important pathway. Therefore, time-dependent variations in observed TC, TF and CF should be expected if radioactive particles are present.

3 SAMPLING AND PREANALYSIS STRATEGY

The analytical results and interpretation of data are closely related to the analytical strategy, sampling, fractionation and measurement techniques chosen, and will depend on

- representative sampling and fractionation of samples;
- in situ, at-site or shortly after sampling;
- preconcentration techniques and chemical yields;
- method of analysis, including determination limits, precision and accuracy.
General aspects associated with sampling, speciation and analytical methods have been discussed in several reviews and textbooks. This article will therefore focus on recent developments within the field. To obtain information of radionuclide species in real systems, samples should be fractionated in situ or at-site and storage of samples or manipulations (e.g. preconcentrated water or dried soils) prior to fractionation should be avoided. In addition to characterization of species, information on transformation processes changing the distribution of species over time and kinetics is needed for assessment purposes. Hence, time series should be considered essential. There is, however, still a great need for standardization of sampling and fractionation techniques as quality assurance and accreditation require proper documentation. Furthermore, standard reference material and protocols of relevance for speciation purposes should be developed.

4 FRACTIONATION OF RADIONUCLIDES IN WATER

There are several requirements which should be met by fractionation techniques applicable for speciation purposes:

- fractionation should take place in situ, at-site or shortly after sampling to avoid storage effects;
- rapid fractionation techniques are needed to avoid establishment of equilibria between species retained and species to be separated during the fractionation;
- sorption effects should be minimized;
- clogging effects should be avoided;
- colloids and aggregates in solution should be stable;
- chemical reagents influencing the distribution of species should be avoided.

Owing to the low concentrations of radionuclides in most waters, techniques yielding large fractionated volumes being concentrated prior to analysis are favorable as determination limits are lowered. Size-fractionation techniques allow discrete phases to be retained, leaving mobile and potentially bioavailable LMM species relatively undisturbed. In addition to the analysis of LMM species, information on the size distribution of colloids or particles, structure and morphology, surface distribution of nuclides and oxidation states should also be obtained by further analysis of the retained fraction using advanced solid surface speciation techniques (e.g. electron microscopy with X-ray microanalysis (XRMA), synchrotron-based X-ray microscopic techniques).

A variety of size and charge fractionation techniques have been utilized for speciation studies in the laboratory, while techniques applicable in situ or at-site are more limited (Table 1). Procedures for sampling and characterization of colloidal material have, however, been reviewed.

4.1 Size-fractionation Techniques

Among size-fractionation techniques, filtration, tangential flow ultrafiltration and partially continuous-flow centrifugation meet the majority of requirements for in situ or at-site radionuclide speciation studies in natural waters (Table 1). In situ dialysis for collecting LMM species in waters can only be applied in heavily contaminated areas owing to the low volumes applied. As LMM species are essential for assessing mobility and bioavailability of radionuclides, further fractionation according to charge properties should be applied (section 4.2).

4.1.1 Filtration

Filtration of large water volumes through membranes of various types and pore diameters is most commonly used for the separation of particles larger than 450 nm in natural waters. By interfacing the filtration equipment to a peristaltic pump sampling system, in situ filtration of large volumes is attained. Radionuclides associated with retained particulate material on filters can be measured directly or after radiochemical separations, while nuclides in filtrates can be analyzed after preconcentration. As conventional suction filtration using a vacuum pump is often employed, the pressure should be kept relatively low (20 mmHg) to avoid rupture of algal or bacterial cells.

Experience over decades within trace element speciation has demonstrated methodological effects within conventional filtration, such as clogging of membranes, concentration polarization, sorption of species and salt retention. When clogging occurs due to blocking of pores by large particles or bridging of smaller particles retained within the pores, the effective diameter of the filter pores and subsequently the filtration rate will decrease. Hence, species in the filtrate are no longer defined according to the pore diameter. Introducing stirred cells, clogging and concentration polarization are minimized, but mechanical disruption or dispersion of aggregates (e.g. humic substances) may occur. Cellulose ester filters (e.g. Millipore, 0.45 µm) act as depth filters, and clogging is of less importance than for polycarbonate screen filters (Nuclepore, 0.4 µm). Glass-fiber membranes, being poorly defined with respect to pore diameters, should be avoided in radionuclide speciation studies. In low-turbidity water, the most serious source of error is adsorption of species to equipment surfaces. As adsorption loss depends on physicochemical forms of the radionuclide and surface charge of equipment walls (dependent on material, cleaning procedures), the loss may be difficult to account for. Conditioning the equipment with a sample aliquot will, however, reduce sorption losses.

4.1.2 Tangential Flow Ultrafiltration

Using a peristaltic pump connected with hollow-fiber systems, large water volumes are transferred directly from the sampling depth into the molecular mass discriminator and ultrafiltrates are collected (Figure 4). Consisting of up to 1000 tubes, the effective surface areas of hollow-fiber cartridges are relatively large. Thus, volumes from about 5 L up to hundreds of liters can be processed with fibers, while even larger volumes can be ultrafiltered using tangential cross-flow systems. Cartridges and tangential cross-flow membranes with nominal molecular weight cut-off values in the range 10^3 – 10^5 Da are also available. The pore-size distribution of hollow-fiber membranes is relatively narrow, clogging is negligible owing to the high internal flow and sorption is insignificant when a sample aliquot is used for conditioning purposes. The cross-flow cassette membranes are, however, less well defined and memory effects reflecting internal sorption may influence the results. A mass balance approach can be utilized to account for methodological effects. In situ systems can be utilized for the determination of radionuclides associated with colloidal material in open surface waters such as river and lake waters and seawaters [e.g. Irish Sea (35) Kara Sea (61)]. For waters with limited volumes such as soil waters (30) for effluents from reactors and reprocessing plants (6) (Sellafield, UK; La Hague, France) or for groundwaters, samples are usually collected a short time prior to fractionation.

Other ultrafiltration techniques (e.g. stirred cell, filtration during ultracentrifugation) are frequently applied in laboratories processing highly contaminated solutions [e.g. effluents (37)] or model experiments using radioactive tracers (section 6). Introducing a magnetic stirrer in conventional ultrafiltration, the concentration polarization is favorably suppressed and the membrane clogging reduced, while mechanical disruption of aggregates may influence the results.

![Figure 4](image-url)
4.1.3 Continuous-flow Centrifugation

Colloidal-sized particles sediment during centrifugation by artificially increasing the force of gravity to counteract the viscosity, mutual repulsion, Brownian movement and the force of shear.\(^{53-56}\) As the particle separation is based on differences in sedimentation coefficients, \(K_S\), small, dense particles are separated together with larger, less dense particles. For particles with similar \(K_S\), special consideration must be given to the particle shape (e.g. plate-shaped clay minerals versus rod-shaped viruses), particle charge (e.g. organic coatings), the degree of external or internal water (macroporosity) and the viscosity, which is reduced if the temperature during centrifugation increases. For particles differing widely in \(K_S\), the most serious source of error is the tendency of small, e.g. clay, particles to cohere and form coarser particles. Furthermore, sorption during centrifugation due to transport of species to tube walls is difficult to quantify. Despite these effects, continuous-flow systems\(^{62}\) have previously proved to be a useful system for collecting colloids or particles from large volumes of low-turbidity waters. Hence associated radionuclides can be determined from the retained fraction and further solid surface analysis can be performed.

High-speed centrifugation (about 10000–20000 rpm) and ultracentrifugation (30000–60000 rpm) are frequently applied in laboratory when small volumes are processed. Furthermore, sucrose density centrifugation (high-speed or ultracentrifugation) for the separation of organic and inorganic colloids, in particular microorganisms from clay minerals in natural waters, should be considered potentially interesting for the speciation of radionuclides in waters within contaminated areas.

4.1.4 In Situ Dialysis

Close to release sites where the contamination of radionuclides is sufficiently high (small volumes to be analyzed), in situ dialysis techniques should be useful for the collection of LMM radionuclide species. The technique has previously proved very valuable for the determination of LMM trace-element species in natural waters.\(^{56}\) By inserting dialysis bags (pore-size 1–10 kDa) containing up to 100 mL of deionized water in rivers or lakes under stable conditions, equilibrium between LMM species on both sides of the membrane is assumed to be established within 5–7 days. Then, dialysis bags are collected and LMM species in the dialyze analyzed. In slow-running waters (e.g. groundwater), however, clogging of membranes due to, e.g. algal growth, may seriously influence the results. So far no published data on the in situ dialysis of radionuclides in natural waters seem to be available. However, other dialysis techniques\(^{22}\) have occasionally been applied for fractionation of radionuclide tracers in laboratory studies (section 6).

4.2 Charge Fractionation Techniques

Charge fractionation techniques are well known within radiochemistry\(^{22}\) (e.g. exchange chromatography, liquid–liquid extraction, electrochemical techniques) and are useful for the determination of charged radionuclide species in solution. The techniques are frequently applied in laboratory experiments for concentrating radioactive tracers from solutions. However, for natural water systems large volumes are usually needed owing to low concentrations of radionuclides. In situ or rather at-site fractionation of charged radionuclides from large volumes of waters can be obtained by applying chromatographic techniques\(^{63}\) coupled on-line to a pump system (Table 1). These systems are often used for wastewater cleaning purposes.

4.2.1 Exchange Chromatography

Using cat(an)ion-exchange or chelating resins, simple cat(an)ions initially present in solution, or dissociated from weak complexes or desorbed from solid surfaces, react with the chromatographic reagent and are retained on the resin (electrostatic sorption or chemisorption), while oppositely charged species, neutral undissociated molecules and colloidal material are excluded and eluted.\(^{63}\) Information on species retained can be obtained from direct measurement of resins (e.g. retention of \(\gamma\)-emitters) or indirectly by the difference\(^{64}\) between the total concentration in the sample and the concentration in the eluate (Equation 2):

\[
C_{\text{retained}} = C_{\text{total}} - C_{\text{eluted}}
\]  

(2)

The fraction of radionuclides retained by resins depends on stability constants and the equilibration time. As the interactions of charged species with resins are time-dependent processes, analytical results depend upon the flow rate of solution through the column. Being essentially a slow fractionation procedure, a shift of chemical equilibria during separation may complicate the interpretation of results. As species differing in size are also fractionated according to charge, the result for unfiltered waters will depend on the experimental conditions (e.g. resins, mesh, flow rates) and the results may be difficult to interpret. Resins may act as a filter and if colloids or particles are retained within the resin, the fraction of charged species estimated from eluates may be overestimated. By removal of particles and colloids prior to exchange chromatography, this effect is avoided.

Cation-exchange resins (e.g. Dowex\(^{\text{TM}}\), Chelex\(^{\text{TM}}\), Amberlite\(^{\text{TM}}\)) are frequently applied for retention of positively
charged metal or radionuclide species in fresh waters and seawaters. Anion-exchange resins (e.g. Dowex-1) are often used for the retention of negatively charged radionuclide complexes of, for instance, Pu and other actinides in groundwater. Chelating resins being species specific, e.g. hexacyanoferrate for chelating Cs ions, are most efficient as interferences from other Cs species or other radionuclide cations can be avoided. For neutral radionuclide species, exchange columns or filter cartridges with sorbents (e.g. active carbon) are frequently used, while XAD resins often applied for retention of organometallic species and humic substances should also be considered applicable for radionuclides. For colloids, in particular Pu colloids in seawater, sorption to Al2O3 is claimed by Mitchell et al. to be specific. However, retention of other Pu species cannot be excluded.

To account for methodological effects, a mass balance approach can be utilized. It is also essential to underline the fact that chemical yields obtained for well-defined tracers for optimizing the technique may not be relevant as species in real systems may differ significantly from tracer species added.

4.2.2 Redox Techniques

Already in 1978 differentiation with respect to oxidation state of plutonium species in the Irish Sea was performed using different redox agents prior to the coprecipitation of the reduced forms (Pu3+, Pu4+) on rare earth fluorides. Recent data from the Irish Sea and the English Channel illustrate also that a significant fraction of Pu isotopes is present as colloidal material. Similar principles have been used to distinguish between CoII and CoIII forms in nuclear discharges to seawater. When strong redox agents are added to samples prior to fractionation, however, transformation of species occurs, e.g. species are desorbed from particle surfaces and colloids may dissolve. Ultraviolet (UV) irradiation of acid oxidizing media (e.g. H2O2) has also been recommended for destroying organic material and release associated metals. However, UV irradiation may also influence the size distribution pattern of clay minerals. Therefore, redox agents can be utilized for the determination of total activity concentrations, but should be avoided for speciation purposes.

4.2.3 Combined Fractionation Techniques

Speciation schemes are often based on size (e.g. 0.1–1.0 µm filters) and charge (e.g. chelating, cation-exchange and anion-exchange resins or sorbents) fractionation techniques performed sequentially. Combined techniques, where species are separated according to size in the colloidal range and charge simultaneously, represent a significant improvement within speciation studies (Table 1). When ultrafiltration is interfaced (on-line) with exchange chromatography (e.g. cation, anion, active C sorbent), radionuclides associated with charged and neutral colloidal species (Figure 4) can be differentiated simultaneously. As the sum of fractions should equal the total concentrations, methodological effects can be accounted for. Although filters implanted with exchange resins have been used for trace metals, clogging of filters may easily affect the results.

The use of dialysis bags (e.g. 100 mL) containing chelating agents is a promising in situ technique for radionuclides in contaminated aquatic systems, as species with molecular weights lower than the membrane pores are separated according to charge. Thus, the fraction retained in the resin represents the LMM cationic (anionic) forms present in waters, and interferences from charged HMM forms are avoided. Careful standardization is needed and membrane effects must be controlled. In running water, however, clogging of dialysis membranes should be minimized. So far, no experiments with dialysis bags containing resins have been reported for radionuclides.

In laboratory, several electrochemical techniques (electrophoresis, electrodialysis) have previously been utilized for determining charged species of radionuclides. Today, the combination of advanced separation techniques applicable for identification of radionuclides associated with for instance volatile and non-volatile organic components [e.g. HPLC/ICPMS and LC/MS/MS] should also be encouraged.

5 FRACTIONATION OF RADIONUCLIDES IN SOILS AND SEDIMENTS

Colloids and particles act as transport agents for radionuclides in water systems and soil and sediment act as sinks for many nuclides released from a source. An inhomogeneous distribution of radionuclides (localized heterogeneities) in soils and sediments also indicates deposition of radioactive aggregates and particles. This can most often be confirmed using autoradiography, followed by advanced surface sensitive techniques. Owing to changes in physical and chemical conditions (i.e. pH, Eh) radionuclides can be remobilized with time and contaminated soils and sediments may act as a diffuse source in the future. Thus, information on the distribution of radionuclide species in pore water, distribution of nuclides between solid and solution (Kd) and binding mechanisms is essential for long-term consequence assessments. Determination of the distribution coefficients, Kd, from total activity concentrations gives no information on processes or mechanisms. Based on extraction techniques or model experiments using well-defined tracers,
however, time-dependent distribution functions can be utilized in process-oriented models.

### 5.1 Surface Analytical Techniques

To obtain information on colloid or particle characteristics, several potential surface analytical techniques are available in laboratories (Table 1). However, the need for high sensitivity in the microscale range limits the application of several methods. Autoradiography, scanning and TEM and laser spectroscopy are most useful techniques. In addition, the recent developments within synchrotron-based X-ray microscopic techniques prove very promising.

#### 5.1.1 Autoradiography

Heterogeneities containing localized radioactivity (i.e. hot spots) can be observed within contaminated areas using portable Geiger–Müller tubes or NaI detectors. Then, qualitative autoradiography can be performed by spreading dried samples (soil, sediment, vegetation) on paper or plastic foils which are placed in close contact with an X-ray- or α-radiation-sensitive film for a certain time of exposure. For activity levels in the range ≤ 1–10 Bq, the exposure time may reach several months. Using well-defined point sources, quantitative autoradiography can be obtained.

#### 5.1.2 Scanning Electron Microscopy with X-ray Microanalysis

Structure information of particles identified, for instance, from autoradiography, can be obtained using SEM interfaced with XRMA, as illustrated for a Chernobyl particle in Figure 5(a–f). Prior to analysis, particles mounted on stubs are usually carbon coated to avoid artefacts due to charging. Using the BEI mode, bright areas reflect particle surfaces containing high-atomic-number elements, while the elemental distribution is attained using X-ray mapping. XRMA also provides information

![Figure 5](image-url)
on the elemental composition at specific particle sites. These techniques have been utilized to characterize radioactive particles from different sources, e.g. flake-like uranium fuel particles released under low-temperature conditions from Windscale, UK, and large uranium fuel aggregates and also crystalline and amorphous single fuel particles released at high-temperature from the Chernobyl reactor.\(^{19}\) Although all these are U-fuel particles, their behavior in the environment is expected to be different; the transport of spheres is different from that of flakes and the weathering rates of amorphous structures are significantly higher than those of crystalline phases. Radioactive particles, different from those associated with accidental scenarios, have also been identified in contaminated sediments,\(^{61,68}\) e.g. in the Irish Sea, due to effluents from the Sellafield nuclear installation and in the Stepovogo Fjord at Novaya Zemlya due to dumped radioactive waste.

### 5.1.3 Transmission Electron Microscopy with X-ray Microanalysis

For colloidal radioactive material, TEM interfaced with XRMA can be utilized for structure and elemental analysis. When droplets of water are transferred to coated grids and carefully dried under a UV lamp prior to analysis, electron-dense structures can be recognized, when compared with a blank (distilled water). Thus, electron-dense structures reflect the presence of colloidal material in effluents\(^6\) from Sellafield and La Hague reprocessing plants (Figure 6a and b). XRMA provides information on the element composition while the distribution of element is obtained from X-ray mapping.

### 5.1.4 Laser-induced Spectroscopic Methods

Surface analysis of radioactive species can also be performed using laser-induced spectroscopic methods.\(^4\) Owing to the high sensitivity, the most promising technique so far is LIPAS.\(^69\) Using well-tuned laser beams, absorbed photons excite orbital electrons. By decay, the light-absorbing species are heated, and temperature changes can be detected by piezoelectric crystals. Although these techniques often have been used for the determination of low-level concentrations of radionuclides, in particular transuranic elements such as Pu, the technique should be further improved for speciation purposes.

![Figure 6](image_url)

**Figure 6** TEM of (a) effluent from the La Hague reprocessing plant, France, and (b) two effluents (SIXEP, Seatank) from the Sellafield reprocessing plant, UK.
5.1.5 Synchrotron-based X-ray Microscopic Techniques

Recent developments within sensitive X-ray microscopic techniques for solid surface analysis have recently been reviewed by Adams et al.

Using monochromatic X-ray microbeams, micro-X-ray fluorescence spectroscopy (μ-XRF) and μ-XAS provide information on the elemental distribution on particle surfaces, while μ-XRD gives information on the crystallographic structures on microscopic areas of solid particles. By tuning the energy of the microbeam source and scanning the energy over an absorption edge of an element of interest, X-ray absorption near-edge structure spectrometry (XANES) can be utilized for speciation purposes. From μ-XANES data, the oxidation number and coordination state of the studied atom can be derived, while EXAFS provides information on the number of atoms, the atomic number and the distance to neighboring atoms in the surface of the solid.

In the laboratory, efficient micro-X-ray sources based on rotating-anode tubes equipped with capillary X-ray optics can be applied. However, the third-generation synchrotron radiation sources, yielding high-intensity and highly monochromatic X-ray microbeams, have significantly increased the sensitivity and applicability of X-ray microscopic techniques. Using synchrotron-based XANES, the oxidation states of uranium associated or with components in soils and sediments have been well documented. Recently, different synchrotron-based X-ray microscopic techniques have been combined by utilizing the micro-X-ray beam at the European Synchrotron Radiation Facility (ESRF), France, to study uranium species in micrometer-sized radioactive particles released from the Chernobyl reactor (unpublished work). From μ-XRD different crystalline forms could be identified, while μ-XANES clearly demonstrated differences in oxidation states of U in released UO₂ fuel; reduced U fuel particles were released during the initial explosion while oxidized U₃O₈ particles were released during the fire. Using microtomography and computerized reconstruction of the particle, information on internal cavities and channels due to the formation of volatiles during operation or the accident could also be observed.

5.2 Size Distribution Pattern

Soil or sediment pore waters (Figure 3) are traditionally collected by squeezing or centrifuging cores, preferentially under in situ temperature and redox conditions. In recent years, porous ceramic cup samplers (vacuum pump suction filtration) with a pore diameter of about 1 μm have been more frequently applied for speciation purposes. Alternatively, dialysis bags, containing water or ion-exchange or chelating resins, have been utilized for the collection of LMM positively charged species in soil–water systems. In both cases, time-dependent sorption of species and clogging of pores may significantly affect the results. For radionuclides associated with the sand, silt and clay fractions in soil and sediments, grain size wet sieving, and radioactivity measurements of the obtained fractions can be useful. Furthermore, individual fractions can be subjected to surface-sensitive analysis and leaching experiments can be performed.

5.3 Extraction Techniques – Reversible/Irreversible Sorption Processes

Numerous articles concerning extraction of radionuclides from soils and sediments have been published in recent years. The application of single extractions and sequential extractions has also recently been reviewed by Kennedy et al. Information on reversible (e.g. physical sorption, electrostatic sorption), and irreversible (e.g. chemisorption) interactions of reactive charged radionuclide species, and the degree of binding to natural components in soils or to deposited radioactive particles (Figure 3) can be attained from extraction experiments. A variety of extraction agents have been applied for extracting radionuclides from soils, in particular from agricultural areas, and from sediments. However, the sequential extraction techniques most often used are modified versions of the method described by Tessier et al. A major objective has been to obtain the bioavailable fraction mimicking the plant uptake. However, no extracting agent so far is able to predict plant uptake without large uncertainties. Reversible and irreversible interactions can be distinguished using sequential extraction of radionuclides in soils or sediments, provided that significant artefacts are not produced. To account for differences in the soil chemistry between individual samples, stable isotopes or analogs in the fractions obtained should also be determined.

Comparison of the extraction yields of the radioactive and stable isotopes may also provide information on the degree of isotopic exchange and if the radioactive isotope is associated with particles.

Extraction or sequential extraction techniques performed in laboratories have been subject to criticisms for decades, partly owing to the interpretation of analytical results. Instead of referring to the displacement or dissolution power of the reagents (e.g. pH-sensitive fraction, weakly reduced fraction, weakly oxidized fractions), several authors refer to a presumed mineral phase (e.g. bound to carbonates, bound to Fe and Mn oxides, bound to organics) without proving that the referred phases are present and are fully or partially responding to the specific chemical treatment. Even
though the early sequential extraction schemes were developed to characterize the phases with which contaminants were associated, misinterpretation of data can easily occur. Unless the actual phase is proved to be present, the phrasing should therefore rather refer to the extraction agent applied. Furthermore, the techniques should be standardized if data in the literature are to be compared, and standard reference materials and protocols applicable for speciation purposes should be developed.

5.3.1 Single Extractions of Soil and Sediments

A variety of extraction agents (e.g. electrolytes, complexing agents, acids, redox agents) have been used, and a variety of analytical results have been published. However, the use of an inert, indifferent or weak electrolyte (e.g. 1 M NH₄OAc at soil pH) corresponding to the first step in most sequential extraction procedures has been found useful for studying pollutant and nutrient competition and reversible associations.²⁷

5.3.2 Sequential Extraction of Soil and Sediments

Sequential extractions are useful techniques for studying reversible or irreversible interactions of radionuclides with solid phases, when reagents are chosen to differentiate between binding mechanisms (Table 2):

- reversible physical sorption: indifferent inert non-reacting electrolytes;
- reversible electrostatic sorption: pH effect, competing/complexing ligands;
- irreversible chemisorption: red/ox systems and increased temperature.

It is essential that fresh solids are used and that the solid–solution system is relatively unaffected in the initial steps. Thus, electrolytes (e.g. Ca ions) with significant higher ionic strength than the soil solution should be avoided as an initial step as particles may aggregate.

According to Beneš and Majer,²² desorption mechanisms can be distinguished in displacement reactions; the adsorbed species are displaced by some foreign species and dissolution processes; the physicochemical forms of the desorbed species are changed. By increasing the concentration of an indifferent (inert) electrolyte (e.g. H₂O or NH₄OAc with pH of soils), the fraction of radionuclides which is desorbed by displacement can easily be distinguished from that being released after dissolution induced, for instance, by redox agents. The chosen experimental procedure is crucial for the quality of the analytical results. Using low-speed centrifugation, colloidal material is included in the aqueous phase, whereas with high-speed ultrafiltration most of the colloidal material is included in the solid phase. For organic soils, filtration must often be applied for practical purposes and clogging of filters may occur. The solid: solution ratio is also essential, as interparticle effects may take place at high ratios.

As reversibility is a matter of kinetics, the time needed for reversible processes (e.g. physical or electrostatic sorption) to reach equilibrium may be considerable.⁴³,⁸⁰ Thus, the chosen contact time should at least allow rapid surface processes to occur. However, slow diffusion processes are essential when long-term assessments are to be made. Factors influencing the analytical results (solid:solution ratio, stirring, temperature, separation of phases, time of contact) should be standardized to avoid methodological effects (e.g. coprecipitation) and for comparison purposes. When standardized, the precision of the sequential extraction method has proved to be within 10%.⁴⁴,⁴⁹,⁵⁰,⁷⁴

5.3.3 Reversible Interactions

By successively repeating the inert nonreacting electrolyte extraction (e.g. H₂O, NH₄OAc), the reversibility of physical or electrostatic sorption of macrocomponents and also radionuclides can be demonstrated. For mobile species being reversibly associated with solid phases, the chemical yield of successive extractions with aliquots of the same electrolyte should be close to 100%. By extraction 10 times with water, organic carbon (e.g. humic substances) and probably associated radionuclides are continuously released upon each extraction (Figure 7a). Similarly, 90–100% of ⁹⁰Sr in

| Weak reducing: NH₂OH·HCl in HOAc |
| Weak oxidizing: H₂O₂, pH 2 |
| Strong oxidizing: 7 M HNO₃, 80 °C |
contaminated soils, swamp and sediments collected at Mayak PA, Russia, is steadily released upon successive extractions with electrolytes (Figure 7c). For $^{137}$Cs (Figure 7b), however, a maximum of 1–3% could be considered reversibly sorbed and exchangeable, i.e. present as mobile species.\cite{7} For Chernobyl soils collected in 1989, the fraction of extractable $^{90}$Sr was, however, surprisingly low (Figure 8). Detailed electron microscopy studies and sequential leaching of individual Chernobyl particles and soils containing particles confirmed a very
Sequential extraction of \(^{90}\)Sr, stable Sr and the added tracer \(^{85}\)Sr in soils from Chernobyl.\(^{21}\)

low extractability.\(^{21}\) By following the increase in the NH\(_4\)OAc-extractable \(^{90}\)Sr with time after deposition, the environmental weathering rates of uranium fuel particles could also be determined.\(^{27,81}\) The weathering rates were primarily dependent on particle composition (e.g. structure, oxidation state) and on soil pH.

5.3.4 Irreversible Interactions

Within the sequential extraction scheme, pH is lowered and the redox power is gradually increased. For irreversibly sorbed species (chemisorption) or species incorporated in the mineral lattice (e.g. crystal defects), rupture of chemical bonds is needed if species are to be released.\(^{22}\) However, dissolution processes are usually affected by slow kinetics.\(^{180}\) By successively changing oxidizing reagents, overlapping fractions (low chemical yield in several fractions) may be obtained. Owing to the strong interaction (fixation) to clays, the most effective extracting agent for \(^{137}\)Cs and stable Cs in soil or sediment is usually strongly acidic and oxidizing reagents, e.g. 7 M HNO\(_3\). Unless Sr minerals are present, stable Sr in soils and sediments is usually reversibly associated. Uranium fuel particles are, however, oxidized by H\(_2\)O\(_2\) in HNO\(_3\) and associated radionuclides are mobilized. Hence the distribution of extractable radioactive and stable isotopes of, for instance, Cs and Sr will be significantly different. As demonstrated for soils contaminated with fuel particles collected close to the Chernobyl reactor (Figure 8), the enriched H\(_2\)O\(_2\)–HNO\(_3\) fraction for \(^{90}\)Sr indicates a fuel particle association, and the distribution in extracts is different from that of stable Sr, being NH\(_4\)OAc extractable, and of the added \(^{85}\)Sr\(^{2+}\) ionic tracer. Hence, the weathering rates of fuel particles are a key factor for assessing mobility in soils and uptake of \(^{85}\)Sr in vegetation.

Most extraction schemes involve leaching with strong acid as the final extraction, intended to represent radionuclides associated with the residual mineral fraction. However, mineral phases are attacked at different rates, and temperature and contact time are essential parameters if complete dissolution is to be attained.\(^{21}\) Therefore, care should be taken when the final analysis is based on radiochemical separations (\(\alpha-\) and \(\beta-\)emitters).

6 DYNAMIC MODEL EXPERIMENTS USING TRACERS

Chemically well-defined spectroscopically pure radioactive tracers are efficient tools in radionuclide speciation studies.\(^{22,82}\) \(\gamma\)-Emitting tracer species can be applied in situ using field lysimeters or in the laboratory to study the behavior of radionuclide species with respect to mobility and biological uptake.\(^{43,83}\) Furthermore, \(\gamma\)-emitting isotopes of different elements or present as different species of the same element can be studied simultaneously. Using stable isotopes in field studies, samples have to be collected and analyzed in the laboratory. In the field, major natural conditions (composition, temperature, etc.) are maintained, even though some artefacts (e.g. distortion of water flow pattern) can hardly be avoided. However, most tracer experiments are performed in laboratories, under climate-controlled conditions or at room temperature. A variety of size and charge fractionation techniques are applied in tracer experiments as the volumes involved can be small (Table 1). However, methodological effects can easily affect analytical results when small volumes are involved.

6.1 Distribution of Species

Assuming equilibrium in the studied system, autoradiography, scanning techniques or analysis of withdrawn samples are frequently used to identify the distribution of added \(\beta-\) and \(\gamma\)-emitting tracers. After the Chernobyl accident, laboratory experiments were utilized to improve the predicting power of \(K_d\) values.\(^{41–43}\) Samples of soils and sediments were incubated with synthetic solutions, e.g. synthetic fresh water or Ca and Mg or Na and NH\(_4\) solution containing ionic tracers (e.g. Cs isotopes) for a limited time of contact (e.g. 24 h or 7 days). Then \(K_d\) values for the tracer (and other major components) were determined after separation of solid and solution or after extractions with weak electrolytes.\(^{41}\) Assuming equilibrium between species in solution and species reversibly associated with solids, the observed \(K_d\) for reversible species can be utilized in short-term assessment. Alternatively, a chemical reagent (e.g. AgTU) is added to soil–water mixtures prior to the addition of the Cs tracer, and according to Wauters et al. AgTU masks the edges of illitic clay minerals to prevent the association of Cs ions.\(^{41,84}\) Thus, the concept of the radiocesium interception potential (RIP) of the micaceous frayed-edge sites (FES) of soil
or sediment systems has been widely adopted.\(^{(41,43,84)}\) For soils and sediments RIP may vary by 2–3 orders of magnitude. Based on 133 soil–sediment systems, however, the experimental \(K_{dS}\) for \(^{137}\text{Cs}\) deviate a factor of <3 from the predicted \(K_{dS}\) for 90% of the observations.\(^{(42)}\) Based on this approach, the \(K_{d}\) predictions are based solely on the solid-phase characteristics determined after 24 h of incubation of ionic tracers under laboratory conditions.\(^{(42)}\) Hence slow interactions are not taken into consideration. Furthermore, the \(K_{d}\) values obtained from measurements of samples collected in a field contaminated with particles will be different from those obtained from ionic solutions.

Biotest experiments (plant uptake, animal uptake, uptake in aquatic organisms) are most often performed under laboratory conditions. If uptake and excretion rates are well known, TF, MF or CF can be determined under laboratory conditions. If uptake and excretion uptake in aquatic organisms) are most often performed those obtained from ionic solutions. At the solid–solution interface and within solids, no other techniques can provide kinetic information on transformation processes affecting the distribution of specific radionuclide species added to a system can be followed over time to obtain information on transformation processes affecting the added species and kinetics involved. Especially in heterogeneous systems (e.g. soil–water or sediment–water systems), no other techniques can provide kinetic information of trace chemistry processes taking place in solutions, at the solid–solution interface and within solids over time.

In dynamic experiments using size and charge fractionation techniques, the formation of radioactive colloids or pseudocolloids from tracer (e.g. transuranic elements) solutions with varying composition can be followed over time.\(^{(85)}\) Furthermore, the time-dependent interaction of different species in solution with a variety of solid surfaces can be followed using extraction techniques. Time-dependent interactions of Cs isotopes with solid phases influencing the distribution coefficient \(K_{d}\) in soils have been well documented by Absalom et al.\(^{(43)}\) As demonstrated for marine sediments–seawater systems (Figure 9), the interaction of added \(^{134}\text{Cs}^{+}\) ions with solids followed at least a two-step function: rapid initial surface interaction and probably slow diffusion into double layers of solids.\(^{(86)}\) The interaction and kinetics will depend on the sediment composition and surface structure of the solid phase. Furthermore, interactions and kinetics (Figure 10) will depend on radionuclide species in question, as demonstrated for Pu\(^{3+/4+}\)/Pu\(^{5+/6+}\) and Pu\(^{3+/4+}\)/Pu\(^{5+/6+}\) species added to marine sediments.\(^{(87)}\) The interaction of Pu\(^{3+/4+}\)/Pu\(^{5+/6+}\) with sediments is significantly stronger (higher \(K_{d}\)) than for Pu\(^{5+/6+}\). Dynamic \(K_{d}\) experiments can be combined with sequential extractions to distinguish between reversible and irreversible (slow reversible) association of radionuclides. At different time intervals, aliquots are withdrawn and extracted, and information on reversible (mobile) and irreversible (inert) interactions and kinetics involved can be utilized in kinetic models. As illustrated in Figure 11, the time-dependent association of \(^{134}\text{Cs}^{+}\) ions with solids can be described as a three-box model,\(^{(88)}\) where the kinetics are essential for predicting the soil to water transfer of ionic Cs species.

Similarly, fractionation techniques should be included in biotest experiments, to obtain information on time-dependent uptake of specific radionuclide species. Thus, CF values will vary according to radionuclide species present in the exposure and organisms exposed: high CF is obtained for radocolloids in filtering organisms, whereas low CF is obtained for fish.\(^{(88)}\) Similarly, high CF is obtained for ionic species in fish, but low CF

### 6.2 Kinetics of Transformation Processes

Using size and charge fractionation techniques, changes in the distribution of specific radionuclide species added to a system can be followed over time to obtain information on transformation processes affecting the added species and kinetics involved. Especially in heterogeneous systems (e.g. soil–water or sediment–water systems), no other techniques can provide kinetic information of trace chemistry processes taking place in solutions, at the solid–solution interface and within solids over time.

In dynamic experiments using size and charge fractionation techniques, the formation of radioactive colloids or pseudocolloids from tracer (e.g. transuranic elements) solutions with varying composition can be followed over time.\(^{(85)}\) Furthermore, the time-dependent interaction of different species in solution with a variety of solid surfaces can be followed using extraction techniques. Time-dependent interactions of Cs isotopes with solid phases influencing the distribution coefficient \(K_{d}\) in soils have been well documented by Absalom et al.\(^{(43)}\) As demonstrated for marine sediments–seawater systems (Figure 9), the interaction of added \(^{134}\text{Cs}^{+}\) ions with solids followed at least a two-step function: rapid initial surface interaction and probably slow diffusion into double layers of solids.\(^{(86)}\) The interaction and kinetics will depend on the sediment composition and surface structure of the solid phase. Furthermore, interactions and kinetics (Figure 10) will depend on radionuclide species in question, as demonstrated for Pu\(^{3+/4+}\)/Pu\(^{5+/6+}\) and Pu\(^{3+/4+}\)/Pu\(^{5+/6+}\) species added to marine sediments.\(^{(87)}\) The interaction of Pu\(^{3+/4+}\)/Pu\(^{5+/6+}\) with sediments is significantly stronger (higher \(K_{d}\)) than for Pu\(^{5+/6+}\). Dynamic \(K_{d}\) experiments can be combined with sequential extractions to distinguish between reversible and irreversible (slow reversible) association of radionuclides. At different time intervals, aliquots are withdrawn and extracted, and information on reversible (mobile) and irreversible (inert) interactions and kinetics involved can be utilized in kinetic models. As illustrated in Figure 11, the time-dependent association of \(^{134}\text{Cs}^{+}\) ions with solids can be described as a three-box model,\(^{(88)}\) where the kinetics are essential for predicting the soil to water transfer of ionic Cs species.

Similarly, fractionation techniques should be included in biotest experiments, to obtain information on time-dependent uptake of specific radionuclide species. Thus, CF values will vary according to radionuclide species present in the exposure and organisms exposed: high CF is obtained for radocolloids in filtering organisms, whereas low CF is obtained for fish.\(^{(88)}\) Similarly, high CF is obtained for ionic species in fish, but low CF

for filtering organisms. As also demonstrated after the Chernobyl accident, the uptake of ionic $^{134}\text{Cs}$ ions in domestic animals was significantly higher than $^{137}\text{Cs}$ from Chernobyl-contaminated fodder.$^{(40)}$

### 7 SPECIATION MODELING

In recent years, models based on thermodynamic constants (e.g. stability or complex constants, distribution coefficients, TCs, concentration ratios) have been developed for radionuclide speciation purposes. Usually, input data include the total activity concentration of radionuclides of interest and of selected interacting components in the studied system as well as literature-derived constants. However, several factors may contribute to large uncertainties in the estimates:

- thermodynamic equilibria may not be attained in the studied system owing to slow processes and, especially for unstable mixing zones (e.g. estuaries), such model predictions can hardly be relevant, hence time-dependent functions rather than constants should be derived;
- thermodynamic constants derived from laboratory experiments may not be relevant for natural conditions (e.g. artificial solutions at room temperature);
- literature data may vary considerably (orders of magnitude);
- lack of relevant data on key trace chemistry processes, for instance the behavior of polymers and colloids, implies that most models describe the system only partially.

Hence thermodynamic models predicting mobility and bioavailability of radionuclides from a source may suffer from large uncertainties. To improve the prediction power, experimental information on radionuclide species, transformation and kinetics should be provided and utilized as input data in dynamic models.

### 8 METHODS OF ANALYSIS

Following fractionation of samples, fractions obtained (e.g. ultrafiltrate) or fractions retained (e.g. particles on membranes) are subjected to analysis of radionuclides and other elements of interest. As the concentration of most radionuclides in obtained fractions usually is low, low-level techniques are essential in speciation studies.

#### 8.1 Low-level Radionuclide Measurements

After preconcentration of $\gamma$-emitters from large volumes of fractionated natural waters (e.g. seawater), radionuclides in the concentrate can be determined using high-volume NaI or HPGe detectors. Usually $\beta$- and $\alpha$-emitting radionuclides are analyzed by $\alpha$- and $\beta$-spectrometry or liquid scintillation techniques, after preconcentration with yield monitors and time-consuming radiochemical separations.$^{(58)}$ Using low-level liquid scintillation spectrometers, $\beta$- and $\alpha$-emitting isotopes can be determined simultaneously (e.g. $^{239,240}\text{Pu}$ and $^{241}\text{Pu}$). However, recent developments within sensitive mass spectrometric techniques (ICPMS, AMS) have proved to be an excellent alternative.
8.2 Mass Spectrometric Methods (Inductively Coupled Plasma Mass Spectrometry, Accelerator Mass Spectrometry)

Mass spectrometric methods for determination of very low concentrations of elemental isotopes, and thereby isotopic ratios, have been developed using a variety of ion sources. Among these are thermal ionization mass spectrometry (TIMS) and SIMS, ICPMS and AMS. Although primarily applied to the determination of stable element isotopes and radiogenic isotopes in geological studies, the techniques can equally well be applied to the measurement of activity concentrations of long-lived low-level radionuclides in various samples using “isotope dilution” methods. Excellent reviews of these techniques have been published elsewhere. In recent years, emphasis has been put on the development of ICPMS and AMS techniques applicable in particular for actinides.

8.2.1 Inductively Coupled Plasma Mass Spectrometry

In ICPMS, samples are introduced by means of a nebulizer, graphite furnace or laser (laser ablation). It is assumed that the sample is fully ionized in the plasma (6000–8000 K) before being transferred into the mass spectrometer. Using nebulizer systems for sample introduction, however, particle discrimination may occur. By scanning the mass range within milliseconds, ICPMS acts as a highly sensitive multielemental technique. For transuranic elements ICPMS has proved to be most useful, by distinguishing between low levels of nuclear weapon-derived 239Pu and nuclear fuel cycle-derived 240Pu. Hence the isotopic ratios can be utilized for source identification (“fingerprint”). By interfacing, for instance, chromatographic separation systems (e.g. LC or HPLC) with ICPMS, the extreme sensitivity of the combined system should be well suited for radionuclide speciation studies in the laboratory.

8.2.2 Accelerator Mass Spectrometry

Although not as widespread as ICPMS, AMS offers almost unparalleled resolution, precision and ultralow-level detection limits (from 10⁴ to 10⁶ atoms). The technique requires the preparation of homogeneous solid metallic or metal oxide samples containing the radionuclide of interest together with a suitable isotopic tracer. The ion source is produced by spluttering the solid sample with Cs⁺ ions and injecting the negative ions into the accelerator. The beam is then accelerated towards a high-voltage positive potential, stripped of outer electrons and the positively charged ions formed (up to 13⁺) are accelerated. Then, the isotopes are separated according to their mass/charge ratios in a high magnetic field before counting. The technique has been developed to permit the measurement of heavy radionuclides such as Pu and Np and has been applied successfully to measurement of 240Pu/239Pu isotope ratios in low-level environmental samples.

9 PERSPECTIVE AND FUTURE DEVELOPMENTS

When short- or long-term consequences of radionuclides released to different ecosystems are assessed, the key factors contributing to major uncertainties are poorly defined source term characteristics especially with respect to the physicochemical form of radionuclides, poorly defined time-dependent interactions of different radionuclide species between water and solids [constant distribution coefficients (Kd) for a given nuclide in a defined soil–or sediment–water system] and poorly defined time-dependent transfer of different radionuclide species to biological systems (constant CFs for a given nuclide to a specific organism). As illustrated in Table 3, a release of mobile species will usually imply a low Kd for soils and sediments and a high CF, for instance for fish. If transformation into reactive species occurs with time (e.g. Pu⁴⁺/Pu⁶⁺ reduced to Pu³⁺/Pu⁴⁺), Kd will increase, CF for fish will decrease and the retention in benthic organisms will be the relevant pathway in dose-assessments. Alternatively, if inert radioactive particles are released, the observed Kd values will be significantly higher and CFs (in fish) lower than expected from literature data. When weathering of particles occurs and mobile species are released, Kd will decrease, whilst CF for fish will increase with time. Hence time-dependent changes in the distribution of radionuclide species and subsequently in observed Kd, s and CFs will significantly influence the dose assessments.

Fractionation, identification and characterization of radionuclide species in the environment are still a challenge within analytical radiochemistry. Although the analytical strategy for radionuclide speciation includes fractionation in situ, at-site or shortly after sampling, most emphasis has so far been put on filtration of waters, extraction of soils and sediments and model experiments in the laboratory. In addition, radioactive particles have usually been identified from the emission of high-energy γ- or β-radiation only. Hence, the potential for improvements is substantial. Among size-fractionation techniques, in situ high-capacity ultrafiltration (e.g. tangential flow systems) is favorable as particles, colloids and LMM species in natural waters can be distinguished. By interfacing charge fractionation techniques (e.g. chromatography), information on neutral and positively and negatively charged LMM species can be attained. As LMM species

Raman Spectroscopy: Introduction

Javier Laserna
University of Málaga, Málaga, Spain

Raman spectroscopy comprises the family of spectral measurements made on molecular media based on inelastic scattering of monochromatic radiation. During this process energy is exchanged between the photon and the molecule such that the scattered photon is of higher or lower energy than the incident photon. The difference in energy is made up by a change in the rotational and vibrational energy of the molecule and gives information on its energy levels. From the beginning much of the theoretical and experimental work in Raman spectroscopy was centered on the fundamentals of inelastic scattering and its application for understanding molecular structure. However, as time elapsed Raman spectroscopy became increasingly important for the advancement of chemical measurements. Certainly, Raman spectroscopy has a special significance to the field of analytical chemistry as a whole, not only because of the impact of the technique itself, but also because its development anticipated a revolution in the way analytical measurements were to be made. The revolution was the insertion of powerful physical methods into a discipline that had been primarily pure chemistry.

The genesis of Raman spectroscopy was in the first quarter of the 20th century when the scattering of monochromatic radiation with change of frequency was predicted theoretically by the Austrian quantum physicist Smekal.\(^1\) The scattering of light by various media had long been studied by Rayleigh in 1871, Einstein in 1910 and others, but no change of wavelength had been observed, with the sole exception of certain types of scattering in the X-ray spectral region observed by Compton.\(^2\) With this background, many scientists were surrounding the idea of inelastic scattering, which was first reported in Calcutta by Raman and coworker Krishnan\(^3\) and almost simultaneously by Landsberg and Mandelstam\(^4\) in Moscow in 1928. Two years later, Raman received the Nobel Prize in Physics for the discovery which bears his name since then.

Some historical details of the developments in Raman spectroscopy both from the theoretical and instrumental points of view are summarized in Figure 1. As with many other branches of analytical chemistry, the development of Raman spectroscopy through the years depended largely on the availability of suitable tools, and significant advances have invariably followed the invention of new instruments. This circumstance can be readily recognized by observation of Figure 1. Developments in Raman spectroscopy occurred slowly during the period from 1930 to 1950, with much of the work immediately following its discovery being devoted to fundamental studies. The rich legacy from the efforts in infrared spectroscopy and the Raman work during this period resulted in formalizing a sound model of molecular vibration dynamics, setting the foundation for Raman scattering as a predictive and interpretative class of spectroscopy. Unfortunately, the basic discoveries made during this period were not followed up in chemical measurements until suitable electronic measuring devices were developed much later. When they were available, advances occurred rapidly in all aspects of Raman spectroscopy from data analysis to instrument miniaturization and, in parallel, the capabilities of Raman-based chemical measurements.

The experimental problems of Raman spectroscopy are the low intensity of the inelastic scattering and the much larger intensity of the Rayleigh scattering. This fact has posed several restrictions to the progress of Raman spectroscopy and has configured to a large extent the instrumentation since the beginning of the experimentation to the present. In their earliest experiments Raman and Krishnan used filtered sunlight as a radiation source and detected the Raman lines of some sixty liquids and gases. They observed the scattering light visually, using a set of compensating colored filters to enhance the optical sensitivity. A more definitive spectrum of carbon tetrachloride exhibiting both the Stokes and anti-Stokes lines was recorded photographically using 435.83-nm mercury excitation was published in 1929.\(^5\) It is interesting to note that at these early times, the Raman spectra could be obtained with relatively simpler apparatus than those required for infrared measurements. As a result at the end of the 1930s the situation was that those working on infrared group frequency analysis had often to resort to Raman data collections for reference material since the Raman spectra were more extensive and better catalogued than the corresponding infrared data.\(^6\) Nevertheless, the exposure times for photographically recording the Raman spectra were of several hours.

Early experimental work was directed toward improving the radiation sources. The mercury lamp, filtered to give essentially monochromatic radiation from one of the prominent mercury lines, became the standard source during the 1930s. Later, the mercury Toronto arc lamp became the ultimate source since its introduction in 1952.\(^7\) However, the decisive transformation in the quality of Raman spectra came with invention of the laser in 1960,\(^8\) which was shortly applied as a monochromatic source. In fact, in 1962 Porto and Wood\(^9\) reported the use of a pulsed ruby laser for exciting Raman spectra. The advantages of the laser included its capabilities...
for focusing onto a very small sample, thus enabling excellent spectra to be obtained routinely from materials in short supply. Microgram quantities suffice since then as compared with $10^3 - 10^6$ times these amounts in the pre-laser era. Also, the laser mitigated some problems with stray light, thus improving the detection power and allowing the study of low frequency vibrations. The capabilities of the laser to provide variable wavelength output permitted, in certain circumstances, avoidance of the problems of fluorescence and absorption encountered.
RAMAN SPECTROSCOPY: INTRODUCTION

3

with many samples. Although for many years the laser was the weaker component in terms of durability and reliability of the Raman instrument, during the 1970s most Raman instrumentation used Ar$^+$ lasers of appropriate stability for excitation with the lines of 488 nm and 514.5 nm. Kr$^+$, He–Ne, cadmium and ruby lasers were also widely employed. Following the demonstration of Fourier transform (FT) Raman spectroscopy in 1986, the use of Nd:YAG lasers operating at 1064 nm has been generalized to decrease the fluorescence level. Opto-electronic devices have progressed dramatically in the past decade as a consequence of major achievements in solid-state technology. As a result compact, efficient, and reliable diode lasers are now available from the visible to the infrared that have been demonstrated to work properly in Raman instruments in combination with suitable filter sets.

Raman spectroscopy always had problems with the high level of elastic scattering, in particular for investigation of lines at short Raman shift. The situation has been handled by fitting the monochromator with two or three dispersion stages. The first commercially available double monochromator incorporated into a spectrophotometer was marketed by 1940 and still today double and triple monochromators are used routinely. These systems may reduce the level of Rayleigh scatter by 10 or more orders of magnitude at Raman shifts of only a few cm$^{-1}$. The price paid for this earnings has been an increase in the size and price of the instrument and a decrease in the throughput of the optical system. The search for alternatives has resulted in the development of high efficiency holographic notch filters for rejection of Rayleigh light, which make successive dispersion stages unnecessary, thus increasing significantly the luminosity of the Raman experiment.

Although photoelectric devices were available in recording spectrophotometers by World War II, Raman detection for more than three decades was dominated by photography. Advantage was taken of the capability for light integration of photographic emulsions to mitigate the Raman detection problem. During the 1940s and 1950s much progress was made in electronics and reliable photomultipliers were developed. By 1970, high quality photomultiplier tubes were available and were universally used except for high resolution spectroscopy of gases in which photographic recording was still occasionally employed. Photocathode surfaces with efficiencies of 10–20% in the blue and green parts of the spectrum were used. In the red and near-infrared quantum efficiencies were not much better than 1%. To reduce dark current, photomultiplier tubes with small area photocathodes and cooling capabilities were used. Signals were processed in pulse counting mode and digital-to-analog converted for display on chart recorders. This instrument configuration changed with the advent of array detectors. First was the photodiode array and much later the charge-coupled device (CCD). In fact, although the CCD was invented in 1970 by Boyle and Smith, its use as a detector for Raman spectroscopy was first reported in 1987. The bidimensional capabilities of array detectors make simultaneous time-resolved signal acquisition and imaging possible. The cooling technology is now mature enough to ensure extremely long integration times with a very low dark signal. Since a single reading is needed to process the signal accumulated, insignificant levels of the noise from readings and from electronics are produced.

The use of computers in Raman spectroscopy occurred relatively late as compared with other techniques. This served however to gain a vast amount of technology and experience from other fields. The situation is well illustrated with FT techniques, whose evolution has been closely coupled with the development of digital computers. A primitive way of transforming the interferograms in spectra was the direct recording of the interferometer detector output in a voltmeter or ammeter, the measurement of the peak heights by hand and the completion of the necessary computation. It is clear that the mathematical process as originally devised for taking the FT was extremely long and consumed enormous amounts of time. Progress in interferometric spectroscopy was very limited as a result. Although some work was done on analog computers, the situation improved with the use of digital computers. However its generalized use only came with the development of the fast FT, a method which greatly reduces the number of required operations using the symmetry properties due to the equal steps in both the interferogram and the spectrum to achieve the transform. This method was relatively easily made compatible with the processing capabilities of the personal computers. The result was the commercial development of computer-controlled spectrometers capable of rapid acquiring, computing, and displaying high quality and resolution spectral data. When FT Raman was first demonstrated, all these technological barriers were already overcome.

Of particular significance in recent years has been the application of fiber optics in Raman spectroscopy. Fiber optics, integrated optics and microoptics have been brought to a high degree of refinement which, in combination with diode lasers, expand the analytical capabilities of Raman spectroscopy. Fiber optic probes with an ample variety of designs to satisfy the most difficult sampling demands have been described. As a result sophisticated spectroscopic measurements in traditionally inaccessible environments such as high temperature process streams and hazardous sampling locations are now possible.
CURRENT CAPABILITIES OF RAMAN SPECTROSCOPY

At the time of the Raman discovery, analytical chemistry was dealing with problems associated with the analysis of inorganic materials and analytes using wet chemistry methods. Outstanding precision and selectivity levels were achieved in many cases using a depurate technique of sample manipulation. Although the methods of analysis were discussed in terms of accuracy and representivity (anticipating the current discussion of analytical properties and quality control), chemical analysis was considered primarily an instrument of trade.\(^{14}\) Methods of analysis were carefully chosen on the basis of speed, dependability, and cost. With this panorama, needless to say that little room existed for the use of Raman spectroscopy as an analytical tool. The low efficiency of the inelastic scattering was an added difficulty for the choice of Raman measurements as a viable analytical solution.

The first to recognize that the Raman spectrum could be a powerful resource in chemical analysis was Kohlrausch, who measured the Raman spectra of a wide range of organic compounds as early as in 1931. Later, some qualitative analysis applications were described for monitoring the progress of distillations and for detecting certain chemical groups such as nitriles, conjugated olefins, and aromatics. Soon after the first Raman grating with photodetector detection was described in 1946 a catalog of Raman spectra of 172 pure hydrocarbons was published. From that time up to the current days of powerful analytical techniques, the growth of the analytical applications of Raman spectroscopy has been spectacular, with capabilities for performing conventional analytical determinations and complex measurement tasks. A wide range of measurement techniques for these purposes are available. Figure 2 shows a schematic diagram of the several faces of modern Raman spectroscopy, including its analytical uses and measurement techniques. It can be used for routine qualitative and quantitative measurements of both inorganic and organic materials, and it is successfully employed to solve complex analytical problems such as determining chemical structures. Gases, vapors, aerosols, liquids and solids can be analyzed. As well as room temperature observations, cryogenic and high temperature measurements can be made, including in situ identification and quantitation of combustion products in flames and plasmas. Raman spectroscopy is one of the few spectrochemical techniques amenable to both laboratory and distance measurements. Open-path optical configurations for remote sensing of atmospheric contaminants are available. Also, Raman excitation and collection using optical fibers in combination with chemical sensors have been adapted for process measurements. Raman spectroscopy can take advantage of the convenience of a range of instrumental configurations, from dispersive to interferometric systems, from monochannel to multichannel detection schemes, and a wide choice of laser systems for convenience of excitation and filter units for spectral purification.

A variety of experimental techniques have been developed. In 1953 the first resonance Raman spectra were reported by Shorigin, and since then the use of resonance enhancement to improve the sensitivity of Raman spectroscopy has become a very popular technique, in particular for those researchers interested in biological problems. Stimulated scattering processes based on high order dielectric susceptibility were reported for the first time in 1962.\(^{15}\) Several coherent techniques have been developed, of which the most popular is coherent anti-Stokes Raman scattering, which allow the acquisition of high resolution Raman spectra, not limited by the Raman spectrometer but for the line width of the laser line.

Micro-Raman spectroscopy has evolved rapidly since 1966 when it was pointed out that the intensity of Raman light should be independent of sample volume and should remain essentially constant with decreasing sample size down to the dimension determined by the diffraction limit, and hence the wavelength, of the laser excitation.\(^{16}\) With routine limits of detection in the nanogram range and high molecular selectivity, micro-Raman spectroscopy has now become a major analytical technique of application in both industry and research. Confocal optical designs and imaging capabilities have further extended the power of this approach.

The enormous enhancement of Raman intensity for molecules adsorbed on rough surfaces was first observed in 1974\(^ {17}\) and then explained as a new phenomenon, increasing the Raman cross-section of the adsorbed molecule by 5–6 orders of magnitude.\(^ {18,19}\) The name for this new technique was surface-enhanced Raman spectrometry (SERS). The interest of SERS for analytical purposes resides in its capability to provide information on molecular identity at trace concentration levels.\(^ {20}\)

It is clear from the above that the success of Raman spectroscopy is largely due to successive improvements in experimental techniques and measurement systems. This section is aimed at presenting the current state of the art in instrumentation, assessing the value of established and new instrumental approaches. The section is organized as follows: Dispersive Raman Spectroscopy, Current Instrumental Designs is discussed by N. Quy Dao. Progress in the different components of the spectrometer is emphasized. Next, Fourier Transform Raman Instrumentation is described by H. Edwards. The importance of the technique for the spectroscopic investigation of interdisciplinary problems and the accessories needed for these purposes are illustrated. The article by J. Andrew is devoted to Raman Microscopy and Imaging. Several
approaches for the generation of Raman images are discussed in detail and a comparison is made with different spectral imaging methods. Finally, *Raman Scattering, Fundamentals*, by J. Popp and W. Kiefer, describes linear and nonlinear Raman scattering in both gases and condensed phases.

No attempt has been made to be comprehensive of the broad world of analytical approaches that have derived from the Raman effect. Rather, the section has been designed to give an appraisal of the bases and major means which served to convert Raman spectroscopy in one of the most powerful, versatile and fascinating tools for the investigation of matter.

**REFERENCES**

Raman spectroscopy (RS) is based on an incoherent inelastic scattering process of light by matter, in either its solid, liquid, or gas state. This interaction between ultraviolet (UV), visible (VIS) or near-infrared (NIR) photons with matter gives rise to a Raman spectrum characterizing its different vibrational transitions. These vibrational transitions may be active for the infrared (IR) absorption or the Raman scattering processes, or for both of them, depending on their selection rules and so IR frequencies may be present or absent in the Raman spectrum of a compound and vice versa. IR and RS are therefore closely related.

It is noteworthy that the first Raman spectrometer used by Sir C.V. Raman in 1928 was a dispersive Raman spectrometer (DRS), composed of a mercury lamp when the sun itself was not the exciting source, with a prism monochromator (MC) as the light dispersor and a photographic film as detector. However, it must be emphasized that the Raman effect is extremely weak, and a good Raman spectrum was very difficult to obtain in a reasonable recording time. Progress in the fields of excitation sources, MCs, and of detectors has been constant. Lasers (mainly gas and solid state) are now currently used as sources. Thanks to the considerable improvements in the other components of a Raman spectrometer, the output power of the laser can now be quite low: a few milliwatts for the excitation light is all that is needed to obtain good Raman signals.

As for MCs, the already highly efficient ruled diffraction gratings (RDGs) were followed by the excellent holographic diffraction gratings (HDGs) used in DRSs. Fourier transform (FT) principles have been also developed, giving birth to FT-Raman spectrometers. Hadamard transform principles have also been used to develop new instruments and Hadamard spectrometers are now being designed.

The ever-present photomultiplier tube (PMT) for the VIS range and semiconductors for the NIR region are largely used as detectors, especially for monochannel and FT-Raman detection. Multichannel detectors with very high quantum efficiency (QE) have appeared on the market opening up new avenues for use of dispersive Raman spectroscopy: High speed and/or compact Raman spectrometers, Raman imaging spectrometers, Raman microscopes, and time-resolved Raman spectrometers are now available using dispersive Raman spectroscopy principles.

The Raman technique is one of the most elegant analytical tools:
A Raman spectrum gives rich structural information, useful for both fundamental and applied research. All the states of matter can be studied, whether solid, liquid, gas, glass, or solutions in water and in organic solvents. There are no sampling problems since a raw material can be studied without any preparation of the sample. The quantity needed for an examination may be very small: a few microliters in size, a few milligrams to micrograms in weight, or some tens of parts per million in a mixture; Several derived techniques such as resonance Raman spectroscopy (RRS), time-resolved Raman spectroscopy (TRRS), surface-enhanced Raman spectroscopy (SERS), coherent anti-Stokes Raman Spectroscopy (CARS), hyper-Raman effect, constitute a large panel of methods, where the same instrumentation can sometimes be used giving complementary results. Raman microscopes and Raman imaging spectrometers are also now available, extending the field of exploration to new domains. Optical fibers used to transport the excitation and Raman light make possible both remote and in situ analyses. These instruments are now used in industry. The present article deals with Dispersive RS and current instrumental designs, but does not tackle other techniques such as the FT-Raman and Raman imaging which are treated in other articles in this Encyclopedia.

1 INTRODUCTION

RS results from the Compton effect, which implies an incoherent diffusion light process. Although the Raman effect was discovered in 1928[1–3] and largely studied in research laboratories during the following decade, the technique was then forgotten for about two decades because Raman measurements were delicate and time-consuming owing to the weakness of the Raman signals. In order to record a good Raman signal, the different components of the Raman spectrometer must be very powerful.

DRSs were the first to be built and remain the most common. They are usually composed of a source, a sample compartment, a MC, a detector, and a dedicated microcomputer.

RS found new life in the 1960s with the discovery of lasers. Lasers make ideal Raman sources with their emission of intense, monochromatic, and polarized light. Laser radiation with wavelengths ranging from UV to NIR is now also available, making it possible to obtain the Raman effect of numerous new compounds which could not be studied otherwise. Moreover, laser diodes (LD) can also be used now as Raman sources.

In the same way, the efficiency of MCs has increased greatly and ghosts and stray light were reduced with the arrival of holographic gratings, while the addition of premonochromators (PMC) (interference filters (IFs) and notch filters (NFs) or gratings) greatly improved resolution. Various MC geometries are now available for recording Raman spectra using either monochannel or multichannel detectors.

With the progress of the electronics industry, the detection of very low light levels has become more accurate. New types of very sensitive detector and especially charge-coupled device (CCD) arrays are now available for different ranges of wavelengths including the very interesting NIR region.

Finally, microcomputers have been added to Raman spectrometers to help with both the collection and the treatment of data thus simplifying the task of obtaining a good Raman spectrum.

A Raman spectrum can now be obtained within a reasonable time (a few seconds). With the latest micro-Raman systems, it is easy to identify microsamples (about 1 µm² in volume). TRRS is also available. RRS and SERS are two derived Raman techniques where the presence of traces can be determined at a concentration as low as a few parts per million. New sampling techniques are available and the remote Raman in situ technique utilizing optical fibers to transport the excitation and diffusion light is also being intensively developed.

Progress in instrumentation is constant, and RS is now widely used thanks to its intrinsic advantages and the decreasing cost of instruments, making it a very competitive choice for chemical analyses.

This article is devoted to DRS. Although the different configurations of such an instrument are now well known, various components of DRS have profited from progress in different fields of technology such as optics, electronics, optoelectronics, mechanics, and engineering, giving rise to new Raman sources, detectors, MCs, and sampling techniques. Thanks also to the arrival of powerful microcomputers, several routine tasks can be computer controlled. These are the main subjects treated in the following sections.

2 THEORY AND OPERATING PRINCIPLES

2.1 Physical Principles of Raman Diffusion

The physical principles of RS are treated thoroughly elsewhere in this Encyclopedia, Raman Scattering, Fundamentals. Nevertheless, the fact that the Raman effect
is very weak compared to other spectroscopic phenomena such as absorption, fluorescence, or coherent light diffusion needs to be noted. This is the reason why RS remained underdeveloped for so long. With the appearance of lasers, monochromatic, well polarized, and eventually tunable and powerful parallel laser beams constitute a perfect Raman source. Microcomputers also make it possible to control Raman instruments automatically. Most recently, high-performance electronic multichannel detectors\(^4\) have become available. Progress in the making of MCs has also made a giant step. It is now possible to record practically almost all the Raman spectra of compounds that were reputed to be very difficult to obtain. New types of Raman spectrometer such as FT-Raman spectrometers (see Fourier Transform Raman Instrumentation) and Hadamard transform Raman spectrometers\(^5\) have also been conceived, bringing new power to RS.

### 2.2 Some Early Raman Instruments

RS does not need a very sophisticated experimental set-up. It was theoretically predicted by Smekal,\(^6\) while the first experimental proof was given by Sir Chandrasekhar Raman, who employed a very simple DRS with a mercury vapor lamp as its excitation source, a prism as its MC and a photographic plate as its detector. However, to obtain a Raman spectrum, several days were necessary. The first Raman spectrum was obtained with a multichannel instrument!

### 3 RAMAN SOURCES

#### 3.1 Physical Principles of Lasers

The word laser stands for light amplification by stimulated emission (SE) of radiation. Lasers are based on three physical principles: SE, population inversion, and optical resonance amplification.\(^7\)

In contrast to spontaneous emission, where a collection of atoms or molecules in their excited states can randomly emit photons from the excited state to a final state, SE is produced when these atoms or molecules emit their photons prematurely after being hit by photons which have precisely the same energy. SE occurs preferentially in the direction of the applied beam and is perfectly coherent with the primary beam. In practice, a spontaneous emission photon is generated first. This photon releases an avalanche of photons of identical energy by the SE process. The substance in which SE can take place is called an active medium. Usually, the population of excited atoms or molecules at equilibrium is low under normal conditions by virtue of Boltzmann’s law and therefore no SE occurs. It is necessary to raise this population to an appropriate level by optical pumping. This operation can be realized using an electrical discharge in the case of gas lasers or a flashlamp or a diode laser for solid-state lasers. In order to amplify the intensity of the beam, a Fabry–Pérot resonance cavity (FPC) is used. This component has the role of amplifying the stimulated beam in the direction of the resonator axis using two reflective mirrors in precise alignment. While all the spontaneous beams which are off-axis are lost, only the beam on-axis is amplified, thus providing a parallel monochromatic laser beam in this direction. The FPC is so adjusted that only the transverse electromagnetic mode (TEM\(_{00}\)) can oscillate. Figure 1 illustrates the main components of a laser.

A laser beam is characterized by wavelength or frequency, the power, width, and dispersion, and the monochromaticity. It is broadened by various physical processes. As the intensity distribution of the beam is practically gaussian (Figure 2), the dimension of the beam is defined by its radius taken at 1/e\(^2\) of its maximum. The beam so limited contains 95\% of the total energy of the initial beam. The breadth of the distribution at I\(_{0}/2\) is defined as the full width at half-maximum (fwhm) also called linewidth. The monochromaticity is defined by the Q-factor, Equation (1):

\[
Q = \frac{\nu}{\Delta \nu}
\]

where \(\nu\) is the laser frequency and \(\Delta \nu\) is its linewidth.

#### 3.2 Different Types of Laser

##### 3.2.1 Gas Lasers

Rare gas lasers are still the most commonly used in RS, in particular \(\text{He}–\text{Ne}\), Ar\(^+\) and Kr\(^+\) lasers. In some cases, mixed Ar\(^+\)/Kr\(^+\) lasers have also been built in order to obtain more laser lines in the same instrument. In the case of \(\text{He}–\text{Ne}\) lasers, the active medium is Ne while excited He atoms transfer their energy to Ne atoms through collision; the existence of various excited energy levels of...
Figure 2 Gaussian intensity distribution $I(r) = I_0 e^{-2(r/a)^2}$, where $a =$ radius of the laser beam, containing 95% of the total energy of the beam and $\delta \lambda = \text{FWHM}$.

Figure 3 Helium–neon energy level diagram and laser transitions.

Ne gives rise to laser lines by transition to lower levels as shown in Figure 3. These are continuous wave (CW) lasers and the red line at 632.8 nm is routinely used in RS.

In ionized Ar$^+$ lasers, neutral argon atoms (Figure 4) are first ionized and thus pass to the electronic state $3p^5 2P_0$ of Ar$^+$. By continuing the electron excitation, the collisions between Ar$^+$ ions and the energetic electrons populate the 4s and 4p excited levels. Since the lifetime of the 4s level is shorter than the lifetime of 4p, the population of the 4p level increases, and population inversion occurs. The transitions of the two levels 4p$^2 D_0$ and 4p$^2 D_0$ down to 4s$^2 2P$ give rise to the two very strong laser lines of an Ar$^+$ laser: a blue line at 488.0 nm and a green line at 514.5 nm. The single line operation is achieved with an intracavity prism assembly. A Brewster angle prism, set between the cavity and the high reflector, is used as MC, allowing only one laser line (Figure 5b). The linewidth is about 5–10 GHz (i.e. 0.16–0.33 cm$^{-1}$) which is good enough for most routine Raman studies. Two intracavity Brewster angle plates are also added in order to obtain a polarized beam. By tilting the prism, other lines can be obtained. In single-frequency operation, an etalon (which is essentially a bandpass filter) is added and narrower linewidth can be obtained (a few megahertz instead of a few gigahertz) (Figure 5c and d). The $Q$-factor can be as high as $10^8$ in this configuration. These extremely narrow lines are used as sources for high-resolution RS for studying, for example, the rovibrational structures of gas. For broadband operation, the prism is removed (Figure 5a). This can be used as excitation source for dye lasers. The mean beam divergence of a gas laser is about 0.5 mrad.

3.2.2 Liquid Lasers

Liquid lasers are very often tunable lasers, also called dye lasers. Their development is based on the fact that the organic dye solution can absorb strongly in the
VIS spectrum and fluoresce in a broad lower frequency range. The dye solution acts as a gain medium. Upon excitation with the intense pump beam (generally a laser line), a population inversion between the ground and excited states occurs. Relaxation to the quasicontinuum of ground state vibrational levels gives rise to an emission of 100 nm or more broad wavelength range. By inserting a wavelength selective element, the dye laser can be tuned over this wavelength range with linewidths down to a few gigahertz. Interest in these lasers is in the possibility of obtaining a precise desired frequency, chosen in the broad fluorescence band of the dye. Depending on the excitation, dye lasers can be pulsed or CW. Such lasers are easy to realise and Figure 6 shows a scheme of a liquid laser cavity. However, with the arrival of tunable solid-state lasers, dye lasers are less attractive as they are cumbersome and fragile. Dye liquids have a short lifetime and are difficult to

**Figure 5** Different line operations. (a) Broadband operation, (b) single-line operation, (c) single-frequency operation, (d) etalon loss minimum tuned to laser gain maximum. (Reproduced by permission of Spectra-Physics Lasers, Inc.)

**Figure 6** Scheme showing a holographic grating dye cavity for various dyes. \( \theta_0 = \) flat angle incidence. Laser wavelength \( \lambda \) is determined when \( \theta \) obeys the diffraction equation: \( a(\sin \theta + \sin \theta_0) = k \lambda \).
handle. The change of liquid dyes is a time-consuming operation.

Figure 7 gives the principal tuning curves of various dyes excited with either an Ar$^+$ (solid curves) or a Kr$^+$ laser (pale curves).

3.2.3 Solid-state Lasers

Solid-state lasers can be either CW or pulsed. In neodymium lasers, the host lattice for the neodymium ions is either a crystal, usually an yttrium aluminum
garnet crystal (YAG) of formula $\text{Y}_3\text{Al}_5\text{O}_{12}$ (Nd: YAG laser), or an amorphous glass (Nd: glass laser). They can be pumped by a flashlamp or more recently, by high-power diode lasers. The principal line of a Nd laser is situated at 1.064 $\mu$m in the NIR region. Using frequency doublers or triplers (usually a nonlinear single crystal like potassium dihydrogen phosphate (KDP) or lithium niobate crystals), discrete wavelengths at 0.532, 0.355, and 0.266 $\mu$m, respectively are obtained and can be used for excitation in the VIS or UV ranges. Moreover, when associated with dye lasers, various frequency ranges are obtained (0.548–0.580 $\mu$m and 0.274–0.290 $\mu$m).

Other solid-state lasers also have some specific applications in RS.

### 3.2.4 Semiconductor Lasers and Diode Lasers

Semiconductor lasers are based on the fact that electrons from a conduction band can be transmitted down to the stable valence band by emitting laser radiation. As the transition energy is rather small, laser light is situated in the IR region. The resonant cavity can be constituted by the end faces of the semiconductor crystal. Titanium: sapphire is a robust tunable laser capable of delivering powerful bands in the red and NIR regions. Figure 8 shows the tuning curves of a Ti: sapphire CW tunable laser.

Diode lasers, based on the same principles, are small in size and robust. These lasers can be stabilized giving good wavelength and intensity reproducibility. However, the linewidth is large (about 10 MHz) and the beam divergence is high (up to $10^\circ$). The output frequency and amplitude are a complicated function of driving current and temperature at the p–n junction, and mode-hopping can occur when the laser jumps suddenly from the $n$th to the $(n + 1)$th mode of the cavity while tilting the grating or when the temperature varies.

![Figure 8 Tuning curves of Ti:sapphire CW tunable laser.](Reproduced by permission of Spectra-Physics Lasers, Inc.)

#### 3.3 Choice of Lasers for Raman Spectroscopy

Lasers are now the universal sources used in RS, thanks to their particularly interesting properties: power, monochromaticity, polarization, and the possibility of obtaining excitation wavelengths ranging from UV to NIR through the VIS region. Practically, however, only the CW laser is used in conventional spectroscopy or in microspectroscopy; pulsed lasers are used for the TRRS technique. Until the 1990s, gas lasers were largely used by Raman spectroscopists. Solid-state lasers, thanks to their robustness, reliability, and power, have tended to supplant gas lasers. However, stabilized diode lasers when associated with corrective optics like a PMC are the ideal source for the instruments of tomorrow.

It is important to remember that Raman intensity is approximately proportional to the frequency to the power of four and the detector response is better when the photon energy is high. However, other physical factors, including electronic transitions, fluorescence, and thermal decomposition also depend on the energy of the excitation beam. Therefore, when no special problem is encountered (fluorescence, decomposition of the samples), the use of blue and green laser lines is advised.

As progress has been made in the optics of MCs and in the efficiency of detectors, it is not necessary to have high power to obtain very good Raman spectra. Lasers with only low or medium power output (from a few milliwatts to some tens of milliwatts) are largely sufficient for Raman applications and costs have been greatly reduced consequently. Single-mode diode lasers have also been tested successfully. However, because of the instability of these lasers, mathematical treatment has been applied to correct the recorded spectra. (8)

Finally, when a specific wavelength is needed as for RRS, tunable lasers are recommended.

UV excitation is often reserved for special cases to avoid fluorescence and also in the cases like the observation of the hyper Raman scattering (HRS) effect or studies of excited states in TRRS. Electronic transitions are indeed frequent for this frequency range, and resonance and nonlinear effects are often observed.

Table 1 gives some characteristics of different lasers with discrete laser lines and Table 2 gives the most usual wavelengths for Raman studies. Other usual lines are the 1064 nm and its harmonics at 532 nm and 355 nm of CW and pulsed YAG-Nd lasers.

#### 3.4 Precautions in the Manipulation of Laser Radiation

4 DETECTORS

The main problem of detection in RS is the very weak photon signal levels of Raman lines. A good detector needs to be highly sensitive, having a fast response time, good detectivity, a wide linear dynamic range, and high QE over a large frequency range. Although Raman spectra occur over a small range of frequencies in the vicinity of the excitation line, it is interesting when a detector possesses a large response curve as the excitation can vary from the UV to the NIR region. There are two different classes of detector which differ in their physical conception and largely in their use in DRS: the monochannel detectors, that is the PMTs, possess only one detecting element and the multichannel detectors, that is the solid-state array detectors, which have several detecting elements.

The performance parameters of a detector can be defined from the transfer characteristic curve (Figure 9), giving the signal output as a function of the optical input.\cite{9,10}\footnote{Figure 9 Transfer characteristic curve of a detector. The linear dynamic range is limited at the low level by noise, and at the high level by saturation which depends on the impedance $r_L$ of the external circuit. (Reproduced by permission of Oriel Instruments.)} The lower part of the curve (dotted line) represents the detection limit (DL) due to the intrinsic noise of the detector. The upper part (curved line) shows the range where the detector is saturated. The middle part is the linear working range of the detector.

4.1 Photomultiplier Tubes

PMTs are photoemissive detectors. They are essentially composed of two parts: a photoemissive cathode and an...
electron multiplier. When photons with sufficient energy hit the photocathode, electrons are ejected. The primary electrons are focused and accelerated by an electrostatic field towards a series of curved electrodes coated with substances able to emit secondary electrons, the dynodes. The primary electrons are then multiplied to become an electron avalanche at the anode. The photoanodic current must be kept below 1 µA to prevent local heating effects and tube fatigue. The electron-multiplying process introduces the least amount of noise and the stability of the detector depends on the fact that the electron beam must follow fairly exact trajectories. Magnetic shields are included in order to increase the stability of the response. Moreover, cooling by Peltier effect diminishes the dark current of the tube. The response time is about 0.5–1 ns. PMTs can be used in a pulsed mode or in direct current (DC). The responsivity as a function of the wavelength is from 180 to 1100 nm in width, and new PMTs are appearing now up to 1500 nm depending on the model. There are several PMT geometries; Figure 10 shows a plan of an end-on PMT.

4.1.1 Direct Current and Photon Counting Devices

The photoanodic current of a PMT is made up of short pulses. Each pulse results from a train of electrons created at the end of the dynode chain by one electron issuing from the photocathode. With analog methods, the anod current of the PMT is amplified and an average value of intensity is measured during the integration time. Various types of noise are included in the signal, thus diminishing the signal-to-noise ratio (S/N). In the photon converting device (PC) method, only signals with amplitude and duration limited to a predetermined range are considered; in particular the shot noise (the thermal emission of dynodes) is filtered. Therefore only electrons issuing from the photocathode are counted by a numerical counter. The PC method enables very low photon flux, between $10^2$ to $10^5$ photons s$^{-1}$ to be measured.

4.2 Multichannel Detectors

Multichannel detectors are solid-state detectors based on silicon chip technology. They are divided into two classes: photodiode arrays (PDAs) and CCDs. The major differences lie in the sizes of the sensitive elements (pixels), linear for PDA and two-dimensional arrays for CCD, and in the signal-handling and read-out methods.$^{11}$

PDAs are of linear format. Each pixel has a dimension of $25 \times 2500 \mu m^2$. PDAs are available in packages with 128, 256, 512 and 1024 pixels. The individual elements respond to the photon flux by producing photocurrents. Those in turn charge individual storage capacitors. The information is given out in a timed sequence. It is important to note that dark current increases with the integration time and it is necessary to know dark current values for each array so that the integration time can be calculated in consequence.

The two-dimensional CCD arrays are built from square elements of $25 \times 25 \mu m^2$. Some $50\,000$–$1\,000\,000$ pixels ranged in a rectangular array.$^{12}$

Figure 10 Scheme showing a PMT. (Reproduced by permission of Oriel Instruments.)

Figure 11 Layout of multichannel detectors. (a) PDA detector and (b) spectroscopic CCD. (Reproduced by permission of Oriel Instruments.)
When the pixels of the columns are binned, that is when they are grouped together to form a linear array of tall thin elements, CCD arrays function as linear detectors, with enhanced performances. Figure 11 shows the layout of a PDA and a CCD detector. Figure 12 shows comparative S/Ns as a function of the input signal for the PDA and CCD detectors and Table 3 gives the comparison of PDA and CCD specifications (at 600 nm) as an example. Various CCDs have been built giving good responses for the different ranges of wavelength. It is now possible to obtain excellent CCDs for a working range from the UV to the NIR regions but prices are still high.

Figure 13 gives the QE of some PDAs and CCDs as a function of the wavelength range. Typically, CCDs have a sensitivity similar to PMTs but, independently of their multichannel detection possibility, they are not damaged by overexposure to bright light. On a CCD, each pixel is overlaid with a small voltage-carrying element, an electrode. During the illumination of the chip, charges are stored in the pixel well. To collect the data, a sequence of voltages is applied across the electrodes to move the charge row by row down into a shift register at the bottom of the array. This charge is then moved by the same means horizontally to the output node where it is converted to a digital form for processing. This readout method gives extremely low read-out noise, and good separation between signal channels (Figure 14).

CCDs are now largely used for multiplex, fast RS and Raman imaging. The very high QE of the silicon is not obtained practically on the commercial CCD, this is due to the different layers and “drains” and the technology and the manufacture of the chips. But some manufacturers propose use of a “back thinned” CCD: the CCD is thinned chemically and irradiated directly on the silicon on the back side of the detector. This detector is near the theoretical QE.

### 4.3 Different Types of Noise in Detectors

When choosing a detector, it is particularly important to know the physical origins of noise in order to avoid it whenever possible. Noise can be extrinsic or intrinsic to the measurement system.

Extrinsic noise involves the transfer of energy from the surroundings to the measurement system and occurs usually in specific frequency ranges. Electric and magnetic fields, radiant energy, mechanical vibration, and cosmic rays can create perturbation. Shielding and grounding the instruments minimizes this kind of noise.

</table>
Intrinsic noise has diverse origins:

- **Thermal noise**, also known as Nyquist or Johnson noise, is caused by fluctuations caused by the thermal motion of electrons in resistive components. It exists even in the absence of current flow and is represented by Equation (2)

\[
V = \sqrt{4kT \rho \Delta f}
\]  

where \( V \) is the average voltage due to the thermal noise, \( k \) the Boltzman constant, \( T \) the absolute temperature, \( \rho \) the resistance of the electronic device, and \( \Delta f \) the bandwidth of the measured frequencies.

Cooling and narrowing the frequency bandwidth greatly reduce thermal noise. Figure 15 shows an example the influence of the temperature on the DL of a PDA detector versus exposure time. At \(-20^\circ\text{C}\), the DL is reached after 10 s of exposure time while at \(20^\circ\text{C}\), noise is much greater and the DL is reached in less than 1 s.

- **Shot noise** is the statistical fluctuation in the process of photoelectron emission in photoemissive detectors and frequently occurs in PMTs. Generation recombination (GR) noise is a kind of shot noise caused by the statistical fluctuation in the number of charge carriers in semiconductor materials, in which both process generation and recombination create fluctuations. Usually, the magnitude of shot noise is much smaller than that of thermal noise. Shot noise is proportional to the square root of the measurement bandwidth \( \Delta f \) and can be reduced by reducing \( \Delta f \).

- **Flicker noise**, commonly referred to as \(1/f\) noise has two different causes, electrical when associated with potential barriers at electrical contacts and optical where it is due to the fluctuations of the source at low frequency. Flicker noise predominates in measurements from 0 Hz (DC) up to about 300 Hz. It can be eliminated by avoiding the use of low-frequency detection.
Figure 16 Example of the response curve using a CCD array detector. The saw profile curve is caused by the readout process which is different for the pair pixels and the odd pixels. Corrections can be made using the spectrum of a white source measured under the same conditions.

For solid-state arrays, two other types of noise can also be defined: pixel noise and fixed pattern noise.

solid-state physics, for studies of rovibrational structure of gases, and other fine structure studies using PMTs that are particularly efficient in the VIS range. However, for the NIR range, in particular with a 1064-nm excitation of a Nd: YAG laser, solid-state detectors such as Ge or InGaAs are now preferred. This is often the case for FT-Raman spectrometers.

For routine control or studies not requiring very high resolution but where speed and robustness are priorities, solid-state arrays are greatly preferable. PDAs were used as multichannel detectors in the 1980s but have now been replaced advantageously by CCD detectors despite their somewhat greater cost. Commercial multichannel Raman spectrometers are now almost exclusively equipped with CCDs. As the response of these detectors is extended well into the NIR region, NIR dispersive multichannel Raman spectrometers are being developed concurrently with NIR/FT Raman spectrometers. Raman imaging is also possible with the NIR dispersive multichannel Raman method but the corresponding resolution is not as good as with VIS light. It is limited by the laws of diffraction. The resolution of NIR Raman imaging will always be superior to about 10 µm².

5 MONOCHROMATORS

A MC is the principal part of a DRS. It is composed of several mechanical and optical components. The following sections describe the optical components, that is the filters and the gratings.

5.1 Filters

Filters are often used in optical devices to cut off low- or high-frequency range (long-wave or short-wave pass filter) or to transmit or to cut off a very narrow spectral range (bandpass filter or NF). Generally, a filter correctly used on parallel light gives a high throughput, up to 80% of the incident light.

Absorption filters, long- or short-wave filters can be made of colored glass and are used to eliminate different orders of a grating. They have now been advantageously replaced by IFs.

There are two kinds of IF differing in their manufacturing modes: dielectric multilayer filters (DMFs) and holographic filters (HFs). They can be either edge filters, bandpass filters, or NFs. DMFs are based on the interference phenomenon and are formed by several tens of dielectric film layers. The reflection of the light is assured by the refraction index variation from one layer (high index) to the next (low index), each λ/4 thick. The relatively high reflective index has a square wave profile in a relatively thin layer (ca. 20 µm). HFs are made using holographic techniques, which greatly improves the IF quality. They have a lower average reflective index with a modulation which varies sinusoidally throughout a thick film (>50 µm). When a polychromatic beam hits the filter, interference happens and only the given wavelength beam passes through the filter. For the holographic notch filters (HNFs) in which only a desired narrow wavelength band is absorbed, that is, the notch region, HNFs have uniform transmission, over 70% of the incident light. The cut-on/cut-off edges are very sharp. The notch wavelength range can be tuned by varying slightly the incidence angle of the incident beam. Figure 17 shows the transmittance of a HNF and the influence of the incident angle on the shift of the filtered wavelength range. By increasing the incidence angle, the notch range is red shifted. This characteristic is exploited to lower the recording range near the Rayleigh line. HNF introduces no additional polarization at normal incidence and has a very low effect below 20°.16

It must be noted that each filter works for only one predetermined wavelength and that it is necessary to change the HNF when the Raman excitation is different.

HNFs have very interesting applications in the Raman remote sensor head (see later) and as a very efficient filter element in PMC. Figure 18 indicates a possible set-up for a HNF in the PMC of a Raman spectrograph. HNF plays a double role: reflecting the laser line to the sample and rejecting the Rayleigh line and stray light, while allowing only the Raman spectrum to pass towards the MC stage. As it is a very efficient and narrow bandpass filter, Stokes and anti-Stokes Raman lines can be recorded accordingly. To tune the notch region, spacers can be introduced to change the HNF when the Raman excitation is different.

The advantages of using HNFs are that the Raman spectrographs are more compact, have better throughput than multistage grating systems, and can be less expensive. Problems of polarization are also minimized. The drawback to using filters is the fluorescence due to the gelatin grains when the laser light hits the filter. To minimize this effect, the filter is placed in between two afocal optics and works by transmission.17 It is worth noting that another kind of rejection filter has been successfully applied to filter the Rayleigh line.18,19 This filter is based on a crystalline colloidal array of very small polystyrene spheres with which the Rayleigh light is diffracted according to Bragg’s Laws. This filter is not yet commercially available.

5.2 Gratings

Diffraction gratings constitute the principal part of a MC. A grating consists of a regular array of parallel equidistant “reflective” lines (Figure 19).
Figure 17 The working conditions of a HNF. (a) By varying the incidence beam angle, the cut-off frequency can be tuned for more than 200 cm\(^{-1}\). (b) From 0° to 9°, the OD is higher than 6, allowing a good elimination of the Rayleigh line. (c) Cut-off position as a function of the incidence beam angle. For 9° incidence, the cut-off position is at 170 cm\(^{-1}\). (d) Spectral edge width on the Stokes side. (e) Characteristic curve of a HNF for the optimum angle (9°), compared to the spectrum of the light source without the HNF (baseline). The transmission is higher than 70%. (f) Definition of the spectral edge width: on the Stokes side: 75 cm\(^{-1}\), on the anti-Stokes side: 41 cm\(^{-1}\). (Reproduced by permission of DILOR.)

These lines can diffract light according to the law of diffraction, Equation (3)

\[
\sin i \pm \sin r = \frac{k\lambda}{a} \tag{3}
\]

where \(a\) is the groove spacing in nm, \(i\) is the incidence angle in degrees, \(r\) is the diffraction angle in degrees, \(k\) is the diffraction order, \(\lambda\) is the incident wavelength in nm and ± stand for reflection and transmission, respectively.

If \(n\) is the groove density or number of grooves per length unit, Equation (4)

\[
n = \frac{1}{a} \tag{4}
\]
which gives Equation (5):

\[ \sin i \pm \sin r = kn \lambda \]  

\[ (5) \]

\( i \) being fixed, and for a given \( k \) Equations (3) or (5) give the value of \( r \) where a maximum intensity for wavelength \( \lambda \) is found. For \( k = 0 \), there is no dispersion (zero order). Usually, gratings are used in their first order. In most MCs (see section 5.3), the location of the entrance and exit slits is fixed and the grating rotates around an axis passing through the middle of the grating. The angle \( D_v \), defined by Equation (6),

\[ D_v = r - i \]  

\[ (6) \]

is an instrumental constant fixed by the constructor. The grating equation can then be written as Equation (7),

\[ 2 \sin \frac{i + r}{2} \cos \left( \frac{D_v}{2} \right) = kn \lambda \]  

\[ (7) \]

\[ \] for the same angle \( i \) and at the same angle of observation \( r \) several wavelengths are superimposed in an arithmetic progression \( v_1, 2v_1, 3v_1, \ldots \). It can be seen that if the incident light is a continuum of wavelengths, after dispersion by a grating there can be superimposition of other wavelengths \( \lambda/2 \) in the second order, \( \lambda/3 \) in the third order, for a given position corresponding to the wavelength \( \lambda \). To prevent the superimposition of the different orders, the diffracted radiation must be contained in a maximum interval called the FSR. To eliminate high-order peaks, edge filters are used.

A grating is characterized by its resolution. The resolution is the ability to separate adjacent spectrum
lines. It is generally defined by Equation (12):

$$R = \frac{\lambda}{\Delta\lambda}$$

(12)

$\Delta\lambda$ being the difference in wavelength between two equal intensity spectrum lines that are just separated.

Gratings usually have defects: ghosts and stray light. Ghosts are spurious spectral lines caused by periodic imperfections in the gratings. Stray light comes from two different origins: random nonperiodic vibrations and nonperfect planarity of the reflecting surfaces.

There are two main types of grating distinguished by their fabrication modes. RDGs are made using a ruling engine. A master grating is first built under very rigorous conditions and replicas are reproduced from the master grating. Each grating is individually controlled, and a specification registered certificate giving various characteristics and defects of the grating such as resolution, stray light, and ghosts is delivered. HDGs are made directly by using two monochromatic laser beams producing interference fringes on a photosensitive layer deposited on an optically flat glass. Diffraction gratings can either work by reflection or by transmission.

Efficiency and throughput are the two most important factors in the choice of a grating. Efficiency for various standard gratings varies generally between 50 and 90%. If $\lambda$ is the center of the spectral region of interest, the maximum efficiency of the grating depends on the parameter $\lambda/a$.\(^{(20,21)}\)

Gratings are not equally efficient at all wavelengths for various reasons. The efficiency can be tuned by changing the groove facet angles, or shape and depth. The optimization of efficiency by appropriate groove shaping is known as blazing. The blaze wavelength is the wavelength for which the grating is most efficient.

Figure 20 shows a comparison of the efficiency curves of a RDG and a HDG around the blaze wavelength $\lambda_B$. In the case where $\lambda/a < 0.2$, which is generally the case in the far-UV domain, the absolute efficiency of the RDG and the HDG drops sharply because of the reflecting factor of the coating material. The efficiencies are comparable for the two types of grating.

It is well known that, when the detector is not photographic and when the spectrum studied is continuous, the throughput of an instrument is proportional to the square of the slit width (all other parameters being fixed). Therefore, a larger density of grooves would increase this quantity. Multiplying the groove density creates a much higher level of ghosts and stray light for the RDG while this is not the case for the HDG (Figure 21). At the same time, because of the complete absence of ghost and lower stray light, HDGs generally have a much higher S/N (Figure 22).

Table 5 sums up the general characteristics of RDGs and HDGs.

5.3 Various Monochromator Designs

5.3.1 Principles of a Monochromator

Figure 23 shows a simplified scheme of a MC. The scattered light issuing from the sample is collected by a lens L1 (or a concave mirror) and is focused on the entrance slit. The parallel beam is collected by L2 (or a concave mirror) and falls onto a dispersing device generally constituted by a grating. The dispersed light is collected by L3. The focused diffracted beam passes through the exit slit situated in the focal plane of L3 and is recorded by a monochannel detector during the

5.3.2 Premonochromators for Lasers

Solid-state lasers or diode lasers, except for the most expensive, do not have the exceptional qualities of a gas laser. The tendency is, however, to use them as Raman sources, since they are robust, cheap, and small in size. The relatively large bandwidths, presence of interference lines, and high background level make the use of IFs or PMC preferable.

IFs are simple and efficient but sometimes they are not available for the exact frequency value and the rejection level at few reciprocal centimeters is not sufficient to work at low frequencies.

Small MCs are often associated with the solid-state lasers to obtain an ideal Raman source. Figure 24 shows the effect of such a PMC on the filtering of undesirable laser lines.

5.3.3 Premonochromators for Raman

A PMC for Raman (Figure 25) is used to eliminate the laser line from the Raman spectrum. It must be followed by a spectrograph to disperse the Raman spectrum.

The advantages of PMC are

- good cut-off (5 cm$^{-1}$ from the exciting line);
- no fluorescence;
- easy to adjust the PMC to the exact value of the diode with the same cut-off quality;
- changing the excitation wavelength is easy by rotating the grating.

5.3.4 Monochromators

There are several MC geometries. The most usual ones are shown in Figure 26.

In the Ebert–Fastié system, a single concave mirror is used as collimator and focus lens. This design gives small and compact high-aperture devices ($f/3$ to $f/5$). In the Czerny–Turner mounting, two small concave mirrors replace the simple mirror in the Ebert–Fastié system. The Czerny–Turner system has a low aperture but has better stray light correction and higher resolution. In the case of a Raman spectrograph, lenses can be used in the place of mirrors.
The different characteristic parameters of a MC are summarized in Table 6.

**Figure 24** PMC for a laser. (a) The PMC is also used to adapt the small diameter of the laser beam \( \phi_1 \) of a low-priced laser, and to reduce the divergence of the output beam (\( \phi_2 \) is fixed by the aperture of the entrance optics). (b) Comparison of the spectra of the laser light obtained without a PMC and (c) with a PMC. (Reproduced with permission of DILOR.)

**Figure 25** A PMC for Raman is a double subtractive spectrometer (no dispersion on the exit plane). (see Figure 27b). The laser line is eliminated by the intermediate slit.

**Figure 26** Some classical geometries of MCs. (a) Mirror spectrometers. UV to IR very good efficiency but optical aberrations (coma and astigmatism). Ideal for spectrometer (or UV/VIS spectrometer). (1) Ebert–Fastié configuration, (2) Czerny–Turner configuration, (3) Littrow configuration. (b) Lens spectrograph: very good optical device (flat field without vignettes). Ideal for multichannel detector.

## 6 RAMAN DEVICES

Raman devices are composed of all the different components described above. The association of these elements forms a spectrometer which must obey specific criteria. Various characteristics of spectrometers are found in Tables 7 and 8 and their defects are defined in Table 9.

### 6.1 Spectrometers and Spectrographs

In the above sections, the principal components and their characteristics are described for users to choose the

* a Any radiation, other than the wavelengths of interest, which passes through the MC to the detection system.

components of the Raman device most suited to their problems.

For RS, in order to obtain the lowest stray light rate, double and triple MCs are mounted. Additive double MCs are generally used for monochannel detection. In this case, the aperture of the slits obeys the following conditions: entrance slit = intermediate slit = exit slit.

The result is a very low back-scattering light (Figure 27a).

For very low frequency Raman a triple additive spectrometer permits coverage of the range from a few cm\(^{-1}\) to 3500 cm\(^{-1}\) including all the laser excitation lines from near-UV to the VIS with a very good resolution using a monochannel detector (Figure 27b).

With a multichannel detector it is necessary to use a double subtractive spectrometer (for all the Raman lines) associated with the spectrograph (Figure 27c) or a NF (for a Raman line) and a spectrograph (Figure 27d). Generally to be stigmatic and to cover the large field for the use of multichannel detectors, the spectrograph is refractive (except for UV Raman spectrographs).

The position of the grating for the determination of the wavelength value is activated by a mechanical system. Figure 28 shows the “sinus bar” geometry, in which wavelengths are linearly related to the screw displacement. Another system is also used in which the cosecant bar gives a linear relation between the wavenumber and screw displacement.

There are several commercial Raman spectrometers available on the market with two main applications. For research applications, there are powerful and even versatile instruments (which are not mutually exclusive) available except for special studies such as CARS or picosecond TRRS. The latter are quite often assembled by physicists in their own laboratories. For industry, the priority is a robust, simple-to-use miniaturized instrument.

Figure 29 shows a diagram of a typical commercial high-resolution Raman triple MC. Figure 30 represents a mixed version spectrometer/spectrograph, using a PMC mounted with a double subtractive grating.

### 6.2 Dispersive Raman Microscopes and Raman Imaging

With the dispersive Raman techniques, one of the most interesting possibilities is the study of microscopic samples even when they are within a transparent solid matrix. There are several specific applications for dispersive Raman microscopes (DRMs), in solid state physics, mineralogy, biology, and industry. With the latest multichannel detectors, Raman imaging can also be realised.

One achievement concerns micro-RS using an optical scanning confocal microscope (SCM). Unlike the conventional optical microscope, where the entire field of view is illuminated and imaged simultaneously, the confocal arrangement uses a point light source sharply focused on a diffraction-limited spot by a microscope lens onto the specimen. The aperture matching of the spectrometer is perfectly adjusted by the special use of a spatial filter, which isolates a region exactly coincident with the illuminated spot through a pinhole aperture.

Figure 31 shows a schematic set-up of a confocal microscope and compares the fwhm with a conventional microscope. This configuration gives improved depth of field and axial resolution, better contrast, and good lateral resolution.

New applications can be found for SCMs, for example the examination of impurities inside a host matrix to determine mineral inclusions in host crystals (Figure 32).

### 6.3 Specific Problems Encountered in Monochromators

#### 6.3.1 Aperture Matching

The GE\(^{22}\) is a constant of a MC system (Figure 33) and the apertures are optically matched when they have the same GE for the whole system Equation (13):

\[
GE = \pi s \sin^2 \frac{\alpha}{2} = \pi s' \sin^2 \frac{\alpha'}{2} = \pi s'' \sin^2 \left( \frac{\alpha''}{2} \right) = \pi s^2 \sin^2 \left( \frac{\alpha^*}{2} \right)
\]  

(13)
Figure 27 Various configurations of spectrometers and spectrographs. (a) Double additive configuration. In this case, the output spectral band from the first MC is dispersed again by a second MC. An additive double MC spectrometer provides approximately twice the dispersion of a single MC. It is also possible to increase the dispersion again by using a third MC. (Triple MC spectrometer of Figure 29). (b) Double subtractive configuration. The narrow portion of the spectrum passing through the exit slit of the first MC is focused again at the exit of a second MC. The dispersion is slightly less than for a single MC owing to instrumental imperfections (alignment, synchronization, aberrations). In order to obtain the spectrum, it is necessary to disperse this portion again by a third MC (see Figure 30). (c) In the case of a spectrograph, a multichannel detector is used. (d) Notch + spectrograph. This configuration gives rise to a very high luminosity instrument. (Reproduced with permission of Oriel Instruments.)

Figure 28 “Sinus bar” geometry. In the case of a double MC, the two gratings are mounted on the same shaft. The axial movement of the trolley corresponds to a rotation of the grating. Following the grating equation $2 \sin (i + r)/2 \cos D_\alpha/2 = k n \lambda$. At the zero order, $(i + r) = 0$. When the grating rotates $\alpha^2$ from its zero position, $(i + r) = 2 \alpha$. As $y/d = \sin \alpha$, the grating equation gives $2 y/d = k n \lambda / \cos D_\alpha$ and $y = k' \lambda$. The horizontal displacement is a linear function of the wavelength. (Reproduced with permission of DILOR.)

For the user, only the entrance optics are interchangeable, while the different instrument apertures are conceived by the constructor. Therefore, when changing a camera lens
for a microscope objective, care must be taken with the aperture matching.

Figure 34 shows a comparison of the collection efficiency of camera lenses and microscope objectives. As a practical consideration, if a sample is opaque or very thin (penetration width of a few microns), it is better to use a microscope objective with high NA. For a slice of silicon, the intensity recorded with an objective ($\times 100$, NA = 0.9) is 23 000 while with a camera lens (50 mm, f/1.4) the intensity recorded is only 130. Conversely, for a transparent sample (calcite crystal) with high penetration depth, it is better to use a small magnification microscope objective ($\times 10$), the signal from a larger volume can then be collected. For the sets of objectives for the calcite crystal, the recorded intensities are respectively 16 000 and 28 000.\(^{23}\)

In this case, the camera objective is better.

6.3.2 Resolution

In single-channel mode, the image of the entrance slit is scanned over the plane of the exit slit. The optimum resolution is obtained when the entrance slit aperture is equal to the exit slit. The slit contribution to the instrument line profile is the convolution of the two slit functions. The line profile is triangular when the exit and the image of the entrance slit widths are equal.\(^{24}\) Figure 35 shows an example of the influence of the slit aperture on the resolution and intensity of DRS Raman spectra. The recording time increases with resolution.

In multichannel mode, the image of the entrance slit is projected onto the two-dimensional detector, with a magnification factor $G < 1$ depending on the optical configuration of the spectrograph. On the detector, the slit function is trapezoidal.
Figure 30 Scheme of a mixed spectrometer/spectrograph. MC1, MC2, MC3 are three MCs, MMS is the micro/macro switch, F1, F2 are filters and S1, S2, S3 are MC slits. Depending on the MMS position, the spectrometer can either function as a triple MC spectrometer together with the PM or a spectrograph with a double PMC in the subtractive geometry and a CCD detector. Figure 31 Schematic set-up of a confocal Raman microscope. The pinhole aperture is placed at the conjugate point of the focus point of the microscope objective. Only the diffused light issued from this point passes through the pinhole. The resolution is greatly increased. (Reproduced with permission of DILOR.)

Figure 32 Raman spectrum of an inclusion of calcite in a ruby host as recorded with a confocal Raman microscope.

6.4 Influence of Excitation Wavelength

The intensity of the Raman bands of a compound depends greatly on the excitation wavelength. Numerous compounds are fluorescent because UV/VIS radiations
for VIS radiations owing to the diverse impurities present in these complex samples. In these very common cases, a change in the VIS radiation to NIR excitation can greatly reduce the fluorescence background. This is the main benefit of NIR excitation (Figure 36). In some other cases, fluorescence is caused by doped ions. The Cr\(^{3+}\) ions of ruby (corundum doped with Cr\(^{3+}\) ions) give rise to a very strong fluorescence, consisting of a very high background and a strong doublet at 692.8 and 694.2 nm in the red region. By exciting with a red wavelength, the Raman spectrum of corundum is recovered with intense fluorescence and is not recordable, while with a green wavelength, good Raman spectra can be obtained as it is far from the fluorescence bands. Figure 37 shows the Raman spectra of a ruby stone with two different excitation wavelengths, in the red region where maximum fluorescence is observed and in the green region where the fluorescence is weaker.

For analytical purposes, it is necessary to be very careful when changing the excitation wavelength. Figure 38
Figure 35 Influence of the slit aperture on the resolution in DRS. When reducing the slit width, the resolution is better while the intensity of the Raman signals decreases. Sample, CCl₄; excitation, 514.5 nm; spectrum from 420–500 cm⁻¹; integration time, 5 s; mode, single-channel sequential; laser power, 100 mW; step, 0.2 cm⁻¹; accumulations, 1.

shows another example, where the Raman spectra of a hard disk recovered with a carbon layer is recorded at the same point with the same optics and with two laser excitations. A doublet is observed for the carbon layer; one at 1368 cm⁻¹ and the other at 1575 cm⁻¹ caused respectively by the diamond-like and the graphite-like vibrations. The fluorescence backgrounds and the relative intensity of the doublet are different and the deconvolution of the band after background subtraction (Figure 39) gives a completely different intensity ratio of the doublet. The inversion in intensity of the two bands is caused by different preresonance intensity enhancements when excitation wavelengths are different.

Therefore, in analytical applications it is highly advisable to use the same excitation wavelength for the measurement of Raman intensity and for the calibration phase.

7 SAMPLING METHODS IN RAMAN SPECTROSCOPY

Sampling in RS can be very simple because the substance can be examined without any preparation. Improvements have been made, however, in order to make it possible to simplify the sampling procedures even more or to increase the potential of the method. Several set-ups are now quite standard.

7.1 Sampling Configurations

The Raman effect is a diffusion phenomenon spread over 4π steradians of space. To collect the Raman effect, various set-ups can be used. The most common ones are 90° collection and back-scattering geometry (Figure 40) and they can be conveniently realised in DRS.²⁵

7.2 Polarization Studies

In studies of liquid and solid substances, it is sometimes important to observe polarization effects. Figure 41 shows the principles of a polarization set-up for studying the polarization of a single crystal. Porto’s notation²⁶ is often adopted in this kind of problem and is shown in Figure 42.

Figure 36 Raman spectra of a black pigment human gallstone using different excitation wavelengths. (1) Excitation line, 1064 nm; Scans, 300; time, 3 s. (2) Excitation line, 632.8 nm; time, 0.1 s; accumulation, 10; grating, 300 lines mm⁻¹; slit, 120; hole, 1000. (3) Excitation line, 514.5 nm; time, 0.1 s; accumulation, 10; grating, 300 lines mm⁻¹; slit, 120; hole, 1000. With NIR excitation (1064 nm), the spectrum of the chemical compound (calcium oxalate) in the calculus is well defined, while with the other two excitation wavelengths in the VIS region, the fluorescence phenomenon completely hides the Raman spectrum of the stone.
Figure 37 Raman and fluorescence spectra of a ruby stone. Grating, 1800 lines mm\(^{-1}\); slit, 120; hole, 1000; no filter; objective, 50.
(a) Time, 5 s; excitation line 514.5 nm; accumulation 35; from 522.5–563.7 nm; condition, notch angle 7.8°. (b) and (c) Time, 0.05 s; excitation line 632.8 nm; accumulation, 10; from 641–751.9 nm; condition, notch angle 11.5°. Ruby is an Al\(_2\)O\(_3\) mineral containing Cr\(^{3+}\) impurities. Ruby gives a very strong fluorescence in the red region due to chromium ion impurities. When excited by red radiation (632.8 nm in wavelength or 15 803 cm\(^{-1}\) in energy), the Raman spectrum of Al\(_2\)O\(_3\) is situated in the region of Cr\(^{3+}\) emission and is completely hidden by the fluorescence spectrum (b, c). Using green radiation (514.5 nm or 19 436 cm\(^{-1}\)), the Raman spectrum of Al\(_2\)O\(_3\), which is far from this region (a) is observed: peaks at 524.7 nm (corresponding to a Raman shift of 378 cm\(^{-1}\)), 525.8 nm (Raman shift \(D = 418\) cm\(^{-1}\)) and 535.2 nm (Raman shift \(D = 751\) cm\(^{-1}\)). Note that the recording time is a 100 times longer for the Raman spectrum (a) than for the fluorescence spectrum, that is the intensity is 100 times weaker for (a) than for (b) using the same ordinate scale.

Figure 38 Raman spectra of a hard disk covered with a carbon layer using two different wavelengths: the background and the intensities of the peaks change greatly. (Reproduced with permission of DILOR.)
It is also worth noting that even with high-NA microscope objectives, the polarization effect is still important and useful for good physical interpretation. (27)

### 7.3 Coupling with Optical Fibers

Raman optrodes using optical fibers have been intensively developed, creating even more applications for RS. Remote and in situ measurements with the possibility of site multiplex are the most important uses of this new technique. As the Raman spectrum is situated in the range where silica has good transmission power, optical sensors have been conceived for miniaturized optrodes and for remote and in situ control using optical fibers. (28–35) Optrodes are increasingly used for routine studies. The physical process of transmission of laser light and collection of the Raman signal with optical fibers is shown in Figure 43. Such an optrode needs two optical fibers, one to transport the excitation radiation and the other to transport the Raman spectrum back to the spectrometer. Appropriate filters are necessary to eliminate the Raman fiber spectrum in the excitation fiber and the collection fiber, respectively. Figure 44 shows some optrode probes which have been tested successfully for Raman applications; some of them are now commercially available, others can easily be home-made. Figure 45 shows a comparison of the performance of some optrodes. Figure 46 shows a diagram of a RLFO installation.

### 8 COMPUTER TASKS

Computers have played an important role in the development of RS. They help to automate several delicate and time-consuming operations, thus improving the manipulation of the instrument.

The microcomputer has different tasks:

- automatic control of the instrument parameters, in particular performing the slit aperture program and moving the cosecant bar for grating wavelength control, recording the detector signal, and presenting the display of the spectrum as a function of the wavenumbers;
- spectrum treatment consisting of operations such as deconvolution, baseline and detector response corrections, addition and subtraction of spectra, decomposition of overlapping peaks, and even holding a library of spectra for identification and analytical purposes.
Figure 41. Polarization set-up for studying a single crystal in 90° scattering geometry. IF is the interference filter used to eliminate the plasma lines of the laser, C is the oriented crystal, V, H polarizers are vertical and horizontal polarizers. Depolarizer is a λ/4 or a scrambler, used to neutralize the polarization effect of the gratings. For a given position of the crystal C (presently X vertical), the following polarizations can be obtained, depending on the position of the λ/2 plate and the V and H polarizers, in the case of a 90° geometry recording.

Figure 42. Porto’s notation. With one single position of the crystal C, four different polarizations can be obtained. In order to obtain the other two polarizations, it is necessary to rotate the crystal. In the case of a back-scattering set-up, only two polarizations are accessible and never the cross-term polarizations.

9 PERSPECTIVE AND FUTURE DEVELOPMENTS

Raman instrumentation is progressing rapidly and intensively. New types of Raman device are being studied and developed. FT-Raman spectrometers are now well established for specific applications, and Hadamard Raman spectrometers are being tested. However, DRS still retains its predominant role. In the UV/VIS region, only dispersive Raman instruments are available until recently and this...
Figure 43 Principle of remote and in situ Raman measurements by optical fibers.

is the reason why FT-Raman spectrometers were first developed, thanks to the well-known Jacquinot (aperture size),\(^{37}\) Fellgett (frequency multiplex),\(^{38}\) and Connes advantages (superimposition and co-adding of spectra)\(^{39}\) of interferometers. However, with progress in CCD technology, NIR multichannel detectors are now available and their performances are remarkable, allowing the extension of dispersive Raman instruments in this region to great advantage. DRMs working in the NIR have only just become available and the specific advantages linked to this method, in particular the ease of changing the excitation lines, the possibility of using diode lasers and solid state lasers open up new applications in this field.

Depending on the specific requirements of the users, the choice of instruments is essential. For physicists who need high resolution, studies of Raman lines near the excitation Rayleigh line, a long focal spectrometer with triple MCs in order to obtain a very high resolution and a low stray light level is advised. Resolution is usually better with monochannel detection, so a photomultiplier with a photon counter is suitable for this kind of study. For TRRS the recording of the spectra needs to be rapid, therefore CCD arrays as detector are often used although more expensive. For industrial applications, resolution is not usually a very important factor. Robustness, rapidity, simplicity, and also cheapness are the main requirements. Very often, a simple HNF as PMC and a HPG as MC is enough for analytical purposes. For routine studies, Raman manufacturers build versatile instruments, grouping a PMC with a double MC in a subtractive configuration, a MC composed of a grating of 300 grooves mm\(^{-1}\) for fast examination of the sample and a grating of 1800 grooves mm\(^{-1}\) for the final Raman spectrum.

Figure 46 Typical RLFO installation.

RS has become a powerful analytical tool offering numerous possibilities thanks to its intrinsic advantages: that is it is nondestructive, sampling is easy, and remote and in situ control are possible for both qualitative and quantitative analyses. For qualitative analyses, Raman spectra in which Raman lines are narrow and well resolved represent the fingerprints of a chemical compound, so the identification of an unknown substance is fast and accurate. Gases, liquids, and solids can be studied by RS and are easily identified. Raman atlases⁴⁰–⁴⁴ are also now available for numerous chemical compounds and can be included in the computer for an automatic search. For quantitative analytical purposes, Raman techniques can now rival other physical methods. The precision is about 1–3% and the DL can be some 10 ppm when special precautions are taken and special optrodes are used. SERS and RRS are the two methods which enable concentrations as little as parts per billion to be measured. For structural studies, high-resolution RS with the possibility of polarization where necessary, makes possible the investigation of vibrational states of gas, liquids, and solids either alone or complementary to IR and neutron diffusion methods. TRRS is one of the most elegant techniques for appraising the structure of excited states of molecules with a timescale down to the picosecond range. To examine small samples, the Raman microscope and especially Raman imaging are very efficient and fast, and distinctive Raman imaging is now a specific analytical technique. Applications are numerous, in physics, chemistry, biology, mineralogy, gemology, chemical industry, food sciences, petrochemistry, nuclear science, in the arts, environment, and so on. For industrial purposes, RS has made an important breakthrough since there is no sampling and the technique is simple and robust, fast, precise, very user-friendly especially when associated with optical fiber sensors, and has a very good quality/price ratio. Added to these qualities is the huge potential of its remote and in situ measurement possibilities. With the introduction of chemometrics for data treatment, complex problems can be solved, the accuracy and the DL have been greatly improved⁴⁵;⁴⁶ and the problem of transferring analytical data sets between instruments is now being treated.⁴⁷

DRSs were the first Raman instruments to be built and with progress in instrumentation, lasers, multichannel detectors, and gratings, they will continue to be of great use in the future especially with the possibility of the interchange of different components. An exhaustive list of commercial Raman instruments is available on the Internet.⁴⁸

Other papers treating the subject “Raman spectrometry” are numerous. A nonexhaustive set of references which can be consulted for more information is given.⁴⁹–⁵³

Other techniques can only complement but not supplant DRS. The future lies in different directions:

- more versatility of DRS instrumentation;
- miniaturization with diode lasers and more robust and compact instruments with high performances are
planned; some portable Raman devices are already available;

- more sensitive detectors to increase the DL in order to achieve TRRS in the picosecond timescale for research in fundamental physics but also to eliminate fluorescence phenomena;
- multiplexing with the help of optical fibers;
- hyphenated analytical methods; Raman spectrometers can be used as detectors for high-performance liquid chromatography;\(^{(54)}\)
- Raman microscopy and imaging in the NIR region.

Fourier Transform Raman Instrumentation

Howell G.M. Edwards
University of Bradford, Bradford, UK

1 Historical Introduction

Since the original discovery by Raman in 1928 of the effect which bore his name, spectroscopists had endeavoured to observe Raman scattering using different wavelengths of excitation. Early restrictions imposed by the photographic plate detectors and irradiance of the sources of radiation effectively led to near-UV, blue and green wavelengths being used and the adoption of mercury arcs, in particular 435.8 and 546.1 nm excitation, as the standard Raman spectroscopic sources of illumination. The search for longer wavelength sources was intrinsically dependent on novel methods of sensitization of photographic emulsions and faster cameras; despite this, some classic work was undertaken using helium lamps and rubidium arcs, which extended the range of excitation sources into the red and made accessible for the first time the recording of Raman spectra of orange and red compounds. The spectroscopic advantages of the interferometer compared with dispersive spectrometers (prisms and gratings) were soon appreciated in the infrared region and in 1964 a seminal paper by Chantry et al. reported the observation of Raman spectra using near-infrared excitation and a Michelson interferometer. However, the inherent weakness of the Raman effect and instrumental deficiencies meant that it was 1986 before FT Raman interferometric spectroscopy using near-infrared excitation was born. In the intervening years, dramatic improvements had been made in radiation sources (lasers), photon detectors, interferometer design and computer-control of Raman spectrometers. It is perhaps also highly significant that the first laser-excited (633 nm) Raman spectrum appeared in this period.

The major advantages of Fourier transform Raman spectroscopy (FTRS) in the near-infrared was quickly identified with fluorescence minimization or rejection and the ability to record spectra from highly colored materials, several disadvantages were noted. Because of the scattering dependence with observed spectral intensity, the Raman effect is some 25 times weaker at 1064 nm in the near-infrared than it is at 488 nm, the blue radiation of an argon ion gas laser. However, the multiplex advantages of interferometric spectroscopy could be used to offset this (see later) – especially through the use of multiple spectral scanning and co-addition by computer-controlled and laser-referenced instrumentation. A more
subtle disadvantage in near-infrared excitation of Raman spectra involved broad-based absorption by atmospheric water vapor or by aqueous media around 1000 nm and Stokes-shifted wavelengths (Figure 1). However, careful experimental arrangements are now possible in which the Raman spectra of aqueous solutions and of hydrated materials can be obtained successfully using 1064 nm excitation; some examples of this will be provided to demonstrate the quality of these spectra which have been obtained despite the presence of water absorption bands. An obvious disadvantage in near-infrared excitation of Raman spectra becomes manifest when heated samples are being studied, or when sample material starts to absorb at the excitation wavelength; the onset of thermal emission as a broad background can be seen (Figure 2), starting at higher wavenumber shifts, but gradually affecting the lower wavenumber region as the sample temperature increases. It is now generally recognized that the upper temperature limit for the recording of FT Raman spectra of heated materials is about 220 °C; this temperature value refers to the observation of low wavenumber shifts and, as expected, the ν(CH) modes of organic compounds in the spectrum are swamped by thermal emission at much lower temperatures.

In this article, the instrumentation required to undertake FTRS will be described; the importance of the technique in furthering applications of Raman spectroscopy to interdisciplinary problems in

archaeological science, environmental science, planetary and extraterrestrial studies, biomedical diagnostics and pharmaceutical science will be illustrated. Several important accessories will be described in relation to some novel spectroscopic problems.

2 EXPERIMENTAL INSTRUMENTATION FOR NEAR-INFRARED FOURIER TRANSFORM RAMAN SPECTROSCOPY

A photograph and schematic diagram of a typical FT Raman spectrometer, in this case a Brüker Equinox 55/S infrared instrument with FRA106 Raman module attachment, is shown in Figure 3. It will be appropriate to describe here the major components of such an instrument and the special accessories which have been constructed to diversify an FT instrument for Raman spectroscopic applications. The other type of FT Raman instrument available commercially is the dedicated, free-standing unit exemplified by the Bruker RFS 100/S system shown in Figure 4.

2.1 Lasers

The selection of a suitable laser wavelength in Raman spectroscopy is normally undertaken with two criteria in mind; the intensity of Raman scattering which can be generated and the avoidance of fluorescence. The former depends on the so-called fourth-power law, in that the intensity of Raman scattered radiation is proportional to $\nu^4$ where $\nu$ is the wavenumber of the laser excitation. With commercial lasers now available from the deep UV
to near-infrared wavelengths, some of which are tunable across the visible region of the electromagnetic spectrum, this means that for similar laser powers, excitation at 250 nm in the UV produces 730 times an intensity of Raman scattering as does excitation at 1300 nm in the infrared, representing the currently used wavelength limits in Raman spectroscopy. Since the Raman effect is so intrinsically weak, therefore, the question should be posed as to why Raman spectroscopists employ instrumentation with near-infrared laser excitation as typified by the topic of this article, FTRS? The answer to this question involves the addressing of the second of the criteria stated above: the minimization of fluorescence – the excitation of which invariably swamps the weaker Raman scattering process. By selection of a laser at higher wavelengths, the energy of excitation is decreased, so that the onset of laser adsorption and the concurrent fluorescence is avoided. This is especially important where complex organic molecules with several low-energy excited states are being studied. Therefore, it is not merely a question of what laser is available and at what cost: the selection of an excitation wavelength is critically important for Raman spectroscopic applications and several examples will be provided to illustrate this aspect. An example is shown for a cyanine dye in Figure 5, excited by lasers operating at 488, 647 and 1064 nm. The move towards longer wavelength visible excitation in Raman spectroscopy is not always successful; even at a helium–neon excitation wavelength of 633 nm, fluorescence can still be troublesome. Using diode lasers at 780 nm or 840 nm, the rejection of fluorescence is better, but now the photodiode detector response to the scattered radiation at these longer wavelengths becomes a problem. This detector efficiency is reduced to almost zero by 1000 nm (1 µm), where the near-infrared properly begins.

The advent of FTRS arose with the ready availability of a Nd³⁺ : YAG (neodymium : yttrium aluminum garnet) laser excitation wavelength in the near-infrared region at 1064 nm; the characteristics of this laser were ideal for Raman spectroscopy in that it was not expensive, and with a frequency of 9395 cm⁻¹ the excitation of fluorescence

Figure 4 Diagram of dedicated, free-standing FT Raman spectrometer; the Bruker RFS 100 system. (Courtesy of Dr. P. Turner, Bruker Spectrospin Ltd., UK.)
from organic molecules was significantly reduced. An example is shown in Figure 6 for scytonemin (1), an important natural product which is highly fluorescent, yet which provides an FT Raman spectrum of excellent quality.

Several other lasers operating at long wavelengths rival the choice of the Nd$^{3+}$:YAG option, but using charge-coupled devices (CCDs) with increased quantum efficiencies of detection; these include the Ti–sapphire laser, tunable from about 700 nm to 1000 nm.

The most recent attempt to record FT Raman spectra at relatively longer wavelengths has been reported by Asselin and Chase$^{(8)}$ who used 1300 nm excitation with a Nd$^{3+}$:YAG laser to record FT Raman spectra of a highly fluorescent polyimide for which Raman spectra at 1064 nm were spoiled by fluorescence emission. The fluorescence was significantly reduced at 1300 nm, but the spectral quality was measurably poorer (Figure 7); this was ascribed to the decrease in Raman scattering intensity between 1064 and 1300 nm ($\times2$), the lower laser power used ($\times20$) and greater background noise in the InSb detector.

Hence, at the current time, the laser of choice for FTRS is the Nd$^{3+}$:YAG system operating at 1064 nm. The laser is optically pumped by either a lamp or a diode system; in both cases, nonlasing lines are present which need to be filtered lest they interfere with the observation of the Raman spectra with the production of so-called laser-line artefacts. A simple optical notch-filter is normally used to filter out these “spurious” features.

Most FTRS is carried out using continuous wave (CW) lasers, in which the stability of the laser minimizes source fluctuation noise$^{(7)}$ and enables the multiplexing of spectral data acquisition to take place. Experiments in FTRS have been carried out with a rapid-pulsing, mode-locked Nd$^{3+}$:YAG laser system operating at megahertz frequencies with relatively slower (kiloherz) detector responses and have been successful. A major advantage in the use of pulsed laser excitation is the rejection of continuous thermal emission from heated samples in the near-infrared (Figure 8); Figure 8 shows the effect of recording the FT Raman spectrum of CaSO$_4$ at 140°C using CW and pulsed Nd$^{3+}$:YAG laser excitation at 1064 nm.

### 2.2 Sample Illumination and Collection Optics

The purpose of the sample illuminator is the imaging of the laser beam onto the sample, the collection of
the scattered radiation and the imaging of this into the interferometer. In FTRS very high imaging and collection efficiencies can be achieved using 180° back scattering and large apertures, commonly f/0.7, often using confocal reflectors. If the quantity of sample solid or liquid is small, little of the scattered solid sample is blocked; however, in certain cases, an off-axis collection system may be used to avoid the problem of sample obfuscation of the scattered radiation.

An important instrumental difference between conventional Raman spectrometers and FT Raman interferometers of relevance to a discussion of sample irradiation and collection arrangements relates to the dimensions of the scattered image that is presented to the interferometer. The slit in a conventional spectrometer is a circular aperture in an interferometer; for a typical interferometer operating at 1 cm⁻¹ resolution in the near-infrared, the dimension of the entrance aperture is about 4 mm for a spot size at the sample of 1 mm contrasted with a nominal slit width of about 100 µm at 500 nm used in a conventional spectrometer with visible excitation, with a focal cylinder “waist” at the sample of 25 µm. Hence, the extreme focusing of the laser beam in FTRS is neither necessary nor desirable, and potentially large power densities at the focus can be reduced with consequent minimization of sample degradation through thermal effects.

2.2.1 Filters

The scattered radiation in an FT Raman spectrum also contains the Rayleigh scattered radiation at the laser frequency; the latter is up to eight orders of magnitude larger in intensity than the Raman scattering, hence it must be removed lest it causes damage to or saturation of

Figure 7 FT Raman spectra of a fluorescent polyimide (a) with 1064 nm excitation and (b) with 1.3 µm excitation. The fluorescence background present at 1064 nm and rejected at 1.3 µm should be noted. (Reproduced by permission from Chase and Rabolt.® Copyright Academic Press.)

Figure 8 FT Raman spectra of calcium sulfate excitation: (a) CW operation; (b) Q-switched pulsed operation. Note the presence of broad-band infrared emission in the upper spectrum which has been effectively discriminated against in the lower spectrum. (Reproduced by permission from Chase and Rabolt.® Copyright Academic Press.)
the detector. Several systems are commonly used for this, including dielectric filtering, in which a multilayer-coated plate is highly absorbing at the laser frequency but transmits at longer wavelengths, typically about $200 \text{ cm}^{-1}$ from the laser line. Because of inherent problems in the generation of spectral features and background “noise” with dielectric filters, other systems have been discussed, such as holographic notch filters with improved spectral performance. An example of the use of such a filter is seen in the FT Raman spectrum of sulfur powder (Figure 2) where the cut-off is below $50 \text{ cm}^{-1}$ from the exciting line. Several sophisticated improvements in optical filter technology involving systems of four interference filters (chevron-type) or semiconductor-edge filters have reduced the cut-off to less than $40 \text{ cm}^{-1}$ from the laser line wavelength.

### 2.3 Michelson Interferometer

The major advantage of FT methods in Raman spectroscopy is undoubtedly the multiplexing of the system compared with the sequential scanning of spectral elements in conventional spectrometer. This multiplex advantage arises from the simultaneous measurement of multiple spectral signals from a single detector signal. The replacement of a conventional diffraction grating by a Michelson interferometer achieved this advantage in a very realizable way. The Michelson interferometer (Figure 9) consists of a beam-splitter set at $45^\circ$ to the beam of scattered Raman radiation, which is thus split into two mutually orthogonal beams. One of these meets a fixed mirror and is returned along its optical path meeting the other beam which has been reflected at a moving mirror—the position of which affects the phase of the resulting signal, the interferogram. The latter is composed of a series of periodic cosine waves whose amplitudes are dependent on the signal intensity. Analysis of the interferograms is accomplished using Fourier transformations.

The spectral resolution of the interferometer is $1/x$, where $x$ is the pathlength of the interferogram; a $0.5 \text{ cm}$ pathlength hence gives a spectral resolution of $2 \text{ cm}^{-1}$ at $1064 \text{ nm}$, the maximum achievable with the Bruker IFS66/FRA 106 instrument described earlier. This can be correlated with a conventional spectrometer resolution of $2 \text{ cm}^{-1}$ at $500 \text{ nm}$, achieved using a slit width of $100 \mu \text{m}$ and a reciprocal linear dispersion of $20 \text{ cm}^{-1} \text{ mm}^{-1}$ with holographic or ruled diffraction gratings as exemplified by a Spex Model 1401 double monochromator.

Since radiation from all spectral elements over the desired wavelength range is measured in one interferogram scan, the signal-to-noise ratio (S/N) can be increased interferometrically (Fellgett advantage) by the rapid coaddition of scans; for example, modern interferometers can achieve 60 interferogram scans per second, and calculation reveals that a 30-min spectral accumulation for a $2000 \text{ cm}^{-1}$ range therefore gives a S/N improvement of about 50 times over the single-scan dispersive system at $1 \text{ cm}^{-1} \text{ s}^{-1}$.

Additionally, because of the longer wavelengths in the infrared region the precision required for the mirror movements is readily achievable. However, because of the sensitivity of photomultiplier and CCD detectors in the visible region, FT methods are not so advantageous and UV/visible spectrometers still tend to be dispersive-grating systems. The near-infrared region shows a large frequency range compared with other electromagnetic spectra considered here, (Figure 10).

For Raman spectroscopy, interferometers have several advantages over monochromators of similar aperture where radiation must pass through narrow slits (typically

![Figure 9](image)

![Figure 10](image)

**Figure 10** Frequency range (cm$^{-1}$) of the electromagnetic spectrum with FT Raman and conventional Raman spectroscopic ranges superimposed. (Reproduced by permission from Chase and Rabolt. Copyright Academic Press.)
50 to 100 µm cm⁻¹ spectral bandpass) compared with the larger optical conductance of an interferometer (the Jacquinot advantage). For a spectral resolution of 4 cm⁻¹, for example, the étendue (radiation throughput) of an interferometer may be 100 times better than that of the monochromator. Other interferometric properties such as the Connes advantage which arises from the coaddition reproducibility and superimposability of data accumulation, means that in the infrared region the interferometer is supreme for Raman-scattering experiments.

Although it is generally recognized that the interferometer is the key optical component in an FT Raman system, the design leaves little room for adaptability or maneuver. The critical parameters in an interferometer are the transmission and the modulation efficiency.

2.3.1 Transmission
The transmission of the instrument is readily evaluated using laser scattering from standard samples using power measurements at the interferometer entrance aperture and at the detector. Typically, transmissions of about 5–20% are experienced for the near-infrared region; major losses in transmission occur at reflective surfaces and diaphragm apertures. Optical alignment is hence critical, especially of beam-splitters, and the cleanliness of optical surfaces is vital; purging of an interferometer using dry, filtered, recycled nitrogen will assist in the exclusion of dust and water vapor, whose infrared absorptions near 1.3 µm can be troublesome.

2.3.2 Modulation Efficiency
This parameter indicates how effectively the scattered radiation can be analysed. Unmodulated radiation does not only result in a decrease in intensity of the collected signal, but also has an adverse effect on noise levels. The beam-splitter efficiency is critical and for a perfect optical component the modulation efficiency is 100%. A significant problem in this regard is the wavelength dependency of the modulation efficiency; however, instrumental efficiencies of about 80% are readily achievable unless broader ranges of spectral coverage are required. Extension of optical range results in a lower modulation efficiency.

2.3.3 Detectors
The requirements of a detector for FTRS are a high quantum efficiency in the infrared and low background noise, and also a useful spectral range which covers as much as possible of the (Stokes) Raman spectrum. For 1064 nm excitation (9395 cm⁻¹), the 0–3600 cm⁻¹ Stokes Raman shift extends to 5800 cm⁻¹. Ideally, a detector should have a high response over the whole range; clearly, in practice, this is not so as Figure 11, which gives the instrument response function for an InGaAs detector at several temperatures, demonstrates. Generally, an extended spectral range will involve an increase in detector noise, which increases the further one goes into the infrared. Cooling the detector to liquid-nitrogen temperatures (77 K) results in significantly lower noise levels, but this is often achieved at the expense of spectral range coverage. For example, Figure 11 shows how the detector sensitivity “cutoff” is decreased from 3400 cm⁻¹ on cooling from 250 K to 77 K. The trade-off is in a five-fold improvement in detector sensitivity for the narrower spectral range observed with a detector maintained at low-temperatures.

3 OPERATION OF A FOURIER TRANSFORM RAMAN SPECTROMETER
Because of the interdependence of laser source, sample alignment, collection optics setting, interferometer and detector, it is vital to undertake the routine set-up and commissioning of an FT Raman spectrometer before experiments are undertaken to ensure that the instrument is operating at its best. In our laboratories, we use a standard sample of rhombic sulfur, S₈, packed into an aluminum cup.
An initial interferogram of sulfur with a recorded amplitude of 32 K counts per second (cps) for the scattered radiation at a laser power setting of 100 mW is typical. Reduction in signal indicates bad interferometer alignment or a misplaced sample illumination and collection optical arrangement. Signal-to-noise measurements on standard spectra will indicate whether or not the detector is operating with maximum efficiency and sensitivity.

The ratioing of the observed signal to a standard, recorded white-light spectrum is strongly advised for quantitative measurements involving Raman band intensities; for this to be effective, an identical or closely similar optical path for the white-light radiation and that of the Raman experiment should be achieved. White-light radiation is usually generated via a swing-in-mirror situated in the interferometer and use of a tungsten lamp source imaged onto a powdered sample of potassium bromide. Another method involves the collection of scattered white light illumination within the interferometer.

Researchers who approach FTRS from a conventional spectroscopic background using visible excitation will find several points worthy of note:

- Because of the intrinsic lower energies of the infrared laser, higher power levels are feasible in FTRS compared with those used in the visible; this is especially important for highly colored, absorbing, materials and biological materials which are subject to partial degradation or even destruction using visible laser wavelengths.

- It is not as necessary to focus the laser beam in the near-infrared interferometric experiments, whereas this is almost mandatory in their visible counterparts – often, this is accompanied by sample heating effects in the visible.

- The Raman spectra from samples at elevated temperatures are not subjected to the effects of background thermal emission as are their counterparts in the near-infrared. For black-body emission to affect sample Raman spectra in the visible region the temperatures must be high; this is not the case for FTRS, where the realistic experimental upper limit for heated samples is approximately 220 °C for the low wavenumber shift region, and even lower temperatures for vibrational modes in the 3000 cm⁻¹ wavenumber shift region.

- Aqueous solutions demonstrate the effect of near-infrared radiation absorption and consequent sample heating which arises from the first overtones of the ν(OH) stretching modes in this region; hence, even if the solute material does not absorb laser radiation at 1064 nm, the aqueous solvent can produce a heating effect.

- In conventional Raman spectroscopy with visible excitation there is frequently a clearly observable spectral improvement in signal-to-noise levels away from the Rayleigh line. Because of the multiflex spectral arrangement in interferometry, however, all signal wavelengths and noise are detected simultaneously. Hence, an interferometer which has not been properly set-up will produce poor signal-to-noise levels throughout the Raman spectra, irrespective of the wavenumber shift region being examined.

4 COMPARISON OF CONVENTIONAL Raman AND FOURIER TRANSFORM Raman SPECTROSCOPY

The point has already been made in this article that for Raman spectroscopic studies the operation of a system with a near-infrared excitation wavelength (e.g. Nd³⁺ : YAG laser at 1064 nm) obviates the problems associated with fluorescence excitation experienced in the blue and green regions of the visible.⁶,¹⁰ This is an advantage for the examination of the Raman spectra of fluorescent organic species such as anthracene and polyurethanes and inorganic materials such as uranium salts. In addition, Raman spectra of highly colored absorbing materials such as potassium permanganate, iodine, and metal phosphines have been obtained for the first time using FTRS with infrared excitation. On the negative side, however the ν⁴ intensity law for Raman scattering means that the intensity of Raman scattering decreases with increase in wavelength from the visible to the infrared; hence, the Raman scattering from 435.8 nm mercury-arc excitation is about 40 times as intense as that from a Nd³⁺ : YAG laser operating at 1064 nm, power for power. With generally lower powers for infrared lasers compared with the argon-ion system operating near 500 nm, this is compounded even further.

Despite this intrinsic disadvantage, however, the speed and ease of sampling occasioned by the FT spectrometers now make these attractive instruments for both Raman and infrared spectroscopic studies of molecular systems. The advent of FTRS and CCD Raman spectroscopy has truly provided a renaissance for the Raman technique through a wider range of applications now available.

The detailed comparison of conventional disperse Raman with the FT Raman spectroscopic technique is difficult because of the correlation of the many instrumental factors involved in each technique. However, the major differences are as follows:

- Moving to near-infrared excitation at 1064 nm from the visible reduces the Raman scattering intensity...
(dependent on the fourth power of the excitation wavelength) by up to 40 times on 435.8 nm excitation.

- An advantage of near-infrared excitation is the reduction in energy of the lasing transition from about 25 000 to 10 000 cm\(^{-1}\), which therefore inhibits the onset of fluorescence; this is of supreme importance in the application of FT Raman techniques to biological materials and to biomedical diagnostics.

- In a scanning Raman monochromator system only a small portion of the dispersed spectrum is analysed at any one time. With the interferometer, however, the Fellgett advantage applies; this is based on the acquisition of all spectral-resolution elements simultaneously. This greater "speed" of acquisition by an interferometer over a dispersing spectrometer is quantified as \(\sqrt{r}\), where \(r\) represents the number of resolution elements in the spectrum.

- The Jacquinot throughput is much greater for the interferometer than for scanning monochromators in any spectral range since the limitation of the spectral slit is removed. The \(J\) stop in a typical interferometer is about 8 mm diameter compared with a typical 0.1 mm (100 \(\mu\)m) slit width in a spectrometer system.

- Internal calibration of the interferometer against a helium–neon laser (Connes advantage) provides exceptional wavenumber reproducibility, which facilitates the superposition of spectral data (accumulation) and data subtraction (background, solvent, etc.). Hence, although all the spectral data in an FT Raman experiment may be provided in one scan of about 2 s, multiple spectral-data accumulation to improve the S/N is desirable. In cases of very weak Raman spectra, especially from biological materials for which the incident laser power has been reduced to less than 20 mW from 1 W to minimize sample degradation, accumulations of many hours duration are acceptably realistic; for example, the first FT Raman spectroscopic analysis of archaeological human tissue of the "Ice-man", a 5200-year-old corpse, has been provided with up to 12 000 accumulations of spectral scans at 4 cm\(^{-1}\) resolution from a 16 mg sample without deterioration of spectral resolution or evidence of sample degradation being observed (Figure 12).\(^{(11)}\)

- A major advantage of Raman spectroscopy generally for sample investigation is the weak Raman scattering from water molecules; hence, for reactions in aqueous solution, biomolecules, and biopolymeric studies, little sample preparation in the form of desiccation or freeze-drying is necessary. This is particularly crucial for the monitoring of living biological systems by vibrational spectroscopy, where infrared-spectroscopic absorption due to water is strong.

However, as shown in Figure 1, the move of excitation wavelength further into the infrared severely restricts the Raman data that can be acquired in the presence of water, because of increased absorption. This will present a severe limitation to longer-wavelength capability for FT Raman excitation. Even at 1064 nm, the effect of higher-overtone water-based absorption on the higher wavenumber shifts will be manifest. For this reason, the substitution of heavy water (D\(_2\)O) is often favored to alleviate partially the absorption problem with 1064-nm excitation in the near-infrared.

- The increased speed of data acquisition and ease of sampling have made the near-infrared excitation of FT Raman spectra attractive for industrial remote-sensing applications; however the extension of FTRS into the realm of fast, real-time data acquisition in nanoseconds is limited by the relatively slow frequency response of the detectors, but time...
resonance Raman spectroscopy; the signal strength of under investigation. This is the situation that occurs in wavelength of laser excitation approaches that of an spectrum is not always applicable, especially when the enhancers on drug-delivery systems quantified.

A major advantage of Raman spectroscopy, whether conventional or FT technique, is the linear dependence on concentration of molecular species and the observed band intensity. Unlike absorption spectroscopy, where the Beer–Lambert law dictates a logarithmic dependency of concentration on absorption intensity, which demands knowledge of the molar absorbptivity for the quantification of spectral-intensity data, the linearity of concentration/intensity dependence in the Raman spectrum provides an excellent means of following the growth or depletion of molecular species during a reaction.

In this way, Raman spectroscopy has been developed recently as a technique for monitoring reaction kinetics of polymerization, such as the living anionic polymerization of styrene and butadiene in hydrocarbon solvents by a butyl-lithium initiator. The information about kinetic and thermodynamic quantities from Raman-spectroscopic measurements in solutions over various temperatures has thus provided detailed information about molecular and species equilibria, the presence of dimers or oligomers in a reaction system, hydrogen bonding in alcohol and water systems, nitrating species in acidic media, and tautomeric stability. All of these applications are of importance in commercial systems and synthetic procedures. An excellent account of the many applications of FTRS to academic, commercial and interdisciplinary problems is provided in the classic work of Hendra et al. Biologically, changes in distribution and composition of amino acid residues in large polypeptides and sulfur bridges in keratotic samples studied by Raman spectroscopy have provided an insight into drug-targeting systems and tissue degeneration, both of which are vital for biomedical diagnostic applications. Likewise, the absorption of drugs across the human skin barrier, transdermal drug delivery, of importance in pharmaceutical therapeutic formulations has been studied successfully by the FT Raman spectroscopic technique and the influence of chemical enhancers on drug-delivery systems quantified.

However, the linearity between the observed intensity and the concentration of scattering species in the Raman spectrum is not always applicable, especially when the wavelength of laser excitation approaches that of an electronic absorption band in the scattering species under investigation. This is the situation that occurs in resonance Raman spectroscopy; the signal strength of Raman scattering from a molecular species is increased by as much as $10^8$, and the spectrum is simplified because only the vibrations associated with the chromophore under excitation are able to generate the signals in resonance. For example, in the case of haemoglobin, laser excitation within the haem absorption (400–600 nm) produces a resonance spectrum that contains only the enhanced signals of the haem ring vibrational modes, and no bands arising from the protein component are observed.

5 SAMPLE ACCESSORIES

5.1 Raman Microscopy

Raman microscopy, representing the marriage of one of the oldest pieces of scientific optical equipment (the microscope) and one of the newest (the laser), was born in the mid 1970s when Delhaye and Dhamelincourt constructed the Raman MOLE (molecular optical laser examiner), which operated in the green region of the visible spectrum. The ability to characterize materials in a very small quantity, nondestructively, and typically in the nanogram to picogram range ($10^{-9}$ to $10^{-12}$ g) and with a viewing “footprint” of only 1 or 2 µm, was appreciated instantly and gave rise to many and diverse applications. With this small size of sample illumination, the potential of Raman microscopy in the area of biological materials was endless; the first Raman spectrum of living cellular material was recorded during this period and Raman imaging was born. However, despite the obvious advantage in being able to record the optical microscopic image and the Raman spectra from spatially resolved specimen areas of about 1–2 µm diameter to give a “chemical signature”, some problems with the technique still surfaced. Many samples, especially those of biological interest, still fluoresced under blue or green laser excitation and the large laser power densities which could be achieved at samples using even moderately powerful microscope objective lenses resulted in sample degradation.

Messerschmidt and Chase first attempted the recording of FT Raman spectra from microsamples using an infrared reflecting microscope and 1064 nm excitation. A typical commercial FT Raman microscope is shown in Figure 13; the principle is common to several instruments in that the laser radiation from the source is brought via an optical cable to the epi-illuminator of an infrared microscope, focused onto the specimen by the microscope objective; this also acts as the collecting lens for the scattered Raman radiation, which is imaged onto a beam splitter and transferred to the interferometer by another optical cable.
The “footprint” for illumination and scattering in the microspecimen in the near-infrared is obviously dependent on the power of the objective lens used; typically, using the highest lens power of 100×, a sample diameter of about 8–10 μm is achievable. Although this is of an order of magnitude larger than its visible counterparts, the advantage of fluorescence rejection still pertains in near-infrared FTRS.

Examples of the use of FT Raman microspectroscopy from our own laboratories are provided by the first successful report of the Raman spectrum of ancient human skin tissue (Figure 12) from the Alpine Iceman (dating from 5200 years ago), the whole sample of which was only 16.2 mg. In Figure 12, characteristic bands due to the proteinaceous and lipoidal modes in the human skin are clearly seen and have enabled interpretations to be made of the survivability of organic materials in burial environments.

In Figure 14 is shown a stack plot of micro-Raman spectra from the Nakhla Martian meteorite, one of only 13 meteorites of the Shergotty–Nakhla–Chassigny type identified as having originated in ejecta from asteroidal impact on Mars. The geological heterogeneity of the specimen is clearly seen and major features can be assigned to olivine, plagioclase and clinopyroxene. (Reprinted from Edwards et al., ‘Comparative Raman Microscopy of a Martian Meteorite and Antarctic Lithic Analogs’, Planetary and Space Science, 47, 356. Copyright (1999) with permission from Elsevier Science.)

Another very important system of environmental importance which has been studied by Raman microspectroscopy in the near-infrared is a cryptoendolith from the McMurdo Dry Valleys in Antarctica (Figure 15). Here, the living biological organism has colored the interior of Beacon sandstone and has adapted its survival strategy to the production of chemicals, including UV-absorbing pigments, water-storage materials, and cryogenic stabilizers, to combat some of the most extreme environmental conditions on this planet; temperatures as low as −50°C, 0% humidity, and an enhanced UV-radiation flux reaching the terrestrial surface due to upper atmospheric ozone deflection. Raman spectroscopic studies of a vertical section of these bio-geological systems have revealed
new information about the colonization processes which have current relevance in the debate about the presence of extinct or extant life on Mars.\(^{(15)}\)

The localized spatial information provided by FT Raman microspectroscopic studies of pigments used by our ancestors in their decoration of churches or caves has forged a new link between science and art/archaeology.\(^{(16)}\) The analysis of the prehistoric cave paintings of the Pecos culture in the Rio Grande/Devils River confluence in North America (Figure 16) has provided novel information about not only the chemicals and minerals used by the ancient artists some 4000 years ago, but also to a hitherto unsuspected ritual in their cave-painting. Figure 17 shows the optical image of a section of a spallated pigmented fragment from Seminole Canyon in which small white particles can be seen embedded in a black pigmented area. The white particles are calcium oxalate monohydrate (whewellite) which is not native to the region’s geology, and is attributed to the ancient artists’ removal of lichenological deposits from rock surfaces prior to the application of the paint. The presence of organic matter inside the black pigmented layer, and not the red ochre found elsewhere in the caves, assisted in the identification of animal bone-marrow, probably bison or deer, which had been mixed with the paint presumably to give some ritualistic significance to the art work.

A recent advance in FT Raman microspectroscopy has been the advent of a confocal microscope sample illumination arrangement; the inclusion of optical apertures and iris diaphragms has resulted in a more precise depth-profiling measurement capability, often of the order of only several micrometers, which opens up novel industrial applications and biomedical diagnostics, particularly in the areas of polymer multicoatings, films and sections of prosthetic implants in healthy tissue (e.g. hip replacement joints with biocompatible coatings).

The coupling of an automated \(x-y\) drive on the FT Raman microscope stage with computerized data storage acquisition has resulted in the provision of two-dimensional “scans” of a fairly smooth sample surface being obtained which reflect surface composition changes. Such an example has been put to good use in the pharmaceutical industry for examination of material heterogeneity; in our own laboratories an example of a crystallite (\(\sim 250\mu m\)) of \(\beta\)-oestradiol, which has separated...
from its carrier gel in a hormone replacement therapy (HRT) patch is shown in Figure 18. The result of an x–y FT Raman microscopic study of this region of the patch is shown in Figure 19; here, the presence of the crystal “impurity” separated from the surrounding gel matrix is clearly seen in the presence of oestradiol bands.

5.2 Remote Sensing Probes

Of equal-ranking importance with microscopes in FT Raman spectroscopic instrumental accessories is the remote-sensing probe; here, the existing laser radiation is brought out of the spectrometer sample illuminator housing via a flexible light-pipe, usually constructed of polymer or quartz fibers; and imaged onto the specimen using a focusing lens. These probes are of two types: contact and noncontact – referring to the specimen/lens distance. The construction of the probe geometry is very important and several possibilities are now in commercial use (Figure 20);(17) all have the common feature that the laser beam is brought in to the focusing lens by a central fiber, leaving the scattered radiation to be collected using a concentric series of fibers situated around the incoming laser beam.

The remote sensing probes currently in use with FT Raman interferometers demonstrate effectively the non-destructive sampling advantage of the technique for industrial or research environments. In addition to the advances which have been reported for industrial sampling of pharmaceutical tablets, gels, pharmaceutical preparations and polymer analysis (including determination of the reaction rates in situ in polymerization reactor systems from species concentration measurements) a most exciting development has arisen in the area of biomedical diagnostics.

Here, remote-sensing probes of up to 1-m long have been used to examine in vivo human tissue (Figure 21) for trans-dermal drug delivery studies and to evaluate the Raman spectroscopic technique as a nonsurgical device for the identification of skin disease and skin cancers (Figure 22). In Figures 23 and 24 novel applications to the study of in vitro samples of human tissue of archaeological significance are demonstrated by the analysis of a human skull from a Romano-British burial site (ca. 1600 years old) and the skin of a 30-year-old woman from the Qilakitsoq ice-mummy burials. Both have provided “first” examples of this type of analysis using a nondestructive spectroscopic technique.(18)
Testament to the interest in remote-sensing accessories for both FT and conventional Raman spectroscopies in biomedical science is provided by several conferences which are devoted to this theme, including BiOS '99 (San Jose, USA) and Winnipeg 2000 (Canada).

5.3 Hot- and Cold-temperature Accessories

As the number and type of samples accessible to FT Raman spectroscopic study increased, so did the
requirement for temperature variability. As with conventional Raman techniques, the ability to maintain samples at low temperature assisted in the recording of good quality spectra, especially in cases where specimen decompositions occurred in the laser beam, even at low nominal incident powers.

Chemical information available from quantitative and qualitative studies at variable temperatures was extremely useful for the characterization of the behavior of ions in solution, phase-transitions in solids and the investigation of crystal-growth phenomena. An early industrial use of this facility was provided by the characterization of the degradation and stability of pharmaceuticals with time, under shelf-storage or different environmental and climatic conditions.

In our laboratories, we have developed an infrared spectroscopic environmental chamber for FTRS which has resulted in several novel applications. In situ examination of chemical or physical changes in materials as a function of temperature in the range 20–220°C (when onset of infrared broad band thermal emission occurs), humidity from 0–100% and with the possibility of utilizing different controlled synthetic atmospheric compositions is achievable. The design of the environmental chamber accessory is shown in Figure 25; a sample of the FT Raman spectra of sulfur recorded in this environmental chamber at temperatures between 25 and 125°C over the wavenumber range 50–600 cm⁻¹ is shown in Figure 26. A detail of the ν(S–S) stretching region of sulfur S₈ during an experiment designed to monitor the rhombic–monoclinic phase change with time at 100°C is shown in Figure 27, in which the quality of the FT Raman spectra obtained from this accessory is demonstrated.

5.4 Other Accessories

There are special cells available for the recording of FT Raman spectra of materials under diverse conditions, including an electrochemical cell, a cryogenic unit and a multisample automatic analyser; the latter holds up to 16
samples which are held in a remote-controlled carousel for the recording of spectra under sequentially identical conditions – particularly useful for pharmaceutical and polymer specimens. A particularly relevant description of ingeniously designed instrumental accessories for FTRS which take into account the very difficult sampling arrangements of commercially available spectrometers is provided by Hendra et al.\(^9\)

The recording of Raman spectra from the gas phase has provided a challenge for FTRS because of the small sample volumes initiated, the intrinsically low concentration of scattering species and the low intensity of Raman scattering in the near-infrared. As a result, vibration–rotation and rotational gas phase studies are still almost uniquely confined to visible excitation where high irradiances are achieved through complex multiple-pass cell geometry and the shrewd use of reflectors, often in an intracavity laser environment. A serious drawback to high-resolution gas-phase studies in FTRS is the laser linewidth at 1064 nm; in contrast, mode-selected argon-ion lasers operating at 488 or 515 nm have achievable spectral linewidths (full width at half-maximum) of 0.005 cm\(^{-1}\). However, there is now a report of the FT Raman study of the NO\(_2\)/N\(_2\)O\(_4\) gas phase equilibrium, which provides an as yet unique example of the application of FTRS to gases where information is not available from other Raman measurements.

Finally, there are also facilities for changing the geometry of sample illumination such that the laser beam is brought to the specimen in a vertical rather than on a horizontal laboratory axis; this, we have found invaluable for the study of extremely fragile, vulnerable samples which cannot be held in the normal configuration. The incident laser can also be brought in at a grazing incidence to the sample, which is essential for the study of thin films and coatings.

### 6 OTHER INSTRUMENTAL FACTORS

In concluding an account of FT Raman instrumentation, it is appropriate that the facilities provided by the data-acquisition services are also considered as, all too often, these are neglected. Hence, the facilities in a modern, multi-tasking, FT Raman spectrometer for spectral smoothing, baseline subtraction of one or more components from a mixture and comparison of a recorded spectrum with a database for chemometric studies are the most important.

To illustrate the observed effect of some of these operations on the observed Raman spectra, several examples have been chosen from our own laboratory studies. Figure 28 shows the effect of spectral data accumulation under identical conditions and spectral averaging: the improvement of S/N, especially in the early stages of signal accumulation, is easily confirmed in a living biological system.\(^{20}\) Incidentally, this stack-plot also demonstrates in a very graphical way that no degradation has occurred during sample irradiation at 1064 nm over a 12-h period. The instrumental internal wavenumber stability over the same period is also obvious from the appearance of the Raman bands, in which no broadening or loss of resolution can be observed.

Figures 29 and 30 show the FT Raman spectra from a study of medieval wall-painting fragments.\(^{21}\) Medieval
Raman Spectroscopy

Figure 28 Demonstration of the effect of cumulative scanning and superposition of spectral data in FTRS on the S/N.

Figure 29 FT Raman stack-plotted spectra of a red-pigmented fragment from the famous “Entombment of Christ” wall painting, ca. 1175, in Winchester Cathedral, compared with red ocher and vermilion (cinnabar), respectively. The pigment from the medieval painting clearly is a mixture of cinnabar and red ocher although adulteration of expensive pigments, such as cinnabar and lapis lazuli, was common. The hierarchical significance of the Christ figure in the painting could also suggest that perhaps a later restoration of the damaged artwork might have been undertaken with adulterated materials in times of economic recession in the cathedral. (Reproduced from Edwards et al. Copyright J. Wiley & Sons Limited. Reproduced with permission.)

Figure 30 FT Raman stack-plotted spectra of a red-pigmented fragment from the much-deteriorated medieval (ca. 1180) wall paintings in Sherborne Abbey. Unlike the Winchester fragment (Figure 31), the Sherborne fragment consists of pure cinnabar (vermilion). (Reproduced from Edwards et al. Copyright J. Wiley & Sons Limited. Reproduced with permission.)

Wall paintings in English churches were practically universal between the twelfth and the early sixteenth centuries. Few survive today in anything like a complete state, and most are in fragmentary form, often discovered during repair works when later coverings of limewash, and paint are removed. Scenes commonly depict biblical stories and representations of biblical characters. Certain saints such as the Virgin Mary, St Christopher and St Anne were popular, whilst the east wall of the nave was often reserved for a Last Judgment, or “Doom” painting, depicting the final day of reckoning with souls being judged and ushered either into Heaven or Hell; graphic depictions of Hell scenes are common.

Conservation of medieval wall paintings is subject to the same basic principles as other branches of conservation: preservation is the prime objective. However one of the main difficulties with mural paintings is that they have been executed as part of a standing building, and have, in effect, become part of the archaeology of the structure. It is therefore of primary importance to determine both the chemical and physical nature of the materials employed, and that of the substrate, in the formulation of a satisfactory conservation strategy. The interaction of pigments with substratal materials is also important.

From the medieval wall-paintings at Winchester Cathedral (Figure 31) and that at Sherborne Abbey, both dating from ca. 1180, our FT Raman studies have shown the different color palettes used; the red pigment in the Sherborne Abbey artwork consists of pure cinnabar, HgS, whereas that at Winchester Cathedral in contrast is a heavily adulterated mixture of red ocher, Fe2O3, and cinnabar. The Raman spectroscopic analysis of wall-paintings involved not only pigments, but the substrates and preparation materials as well. In Figure 32, the Raman spectra of a heterogeneous fragment of Renaissance fresco from the Palazzo Farnese in Caprarola, Italy, painted in 1560 by Zuccari is compared with that...
of the substrate. The FT Raman spectra of the "pigment" therefore contain bands due to substratal minerals as well, and the value of spectral subtraction for the characterization of the pigment is realized. A feature of interest in the subtracted spectra of the pigment is the doublet characteristic of amorphous carbon with components near 1300 and 1600 cm\(^{-1}\); this correlates well with black particles observed visually in specimens under high magnification and may be ascribed to lamp-black or soot, which has been deposited from candles or torches either at the time of application or by later visitors to the site. Features other than pigment and carbon may occasionally be seen in such spectra; an appropriate case is provided by work on the medieval wall-paintings from the Convento de la Peregrina in Sahagun, Spain, where evidence for lichen colonization and biodeterioration has been provided for the first time through FTRS. Bands due to the \(\nu\)(CO) stretching mode of calcium oxalate monohydrate (whewellite) have been identified in certain areas of the wall-paintings and related to lichen invasion through unglazed apertures in the chapel. Another feature of lichen invasion, the ability to mobilize iron in sandstone substrata and hence the production of areas of differential "staining" of substrata, has been identified in the same church through Raman microscopy. In conclusion, the development of FTRS and microscopy with near-infrared excitation has opened up novel applications in areas of biomedical diagnostics, archaeology, art science, forensic science, environmental science and the interaction of biological materials with geological formations. One of the latest applications which is now being considered is the reduction in size and weight of the Raman spectrometer, excitation laser and detector for an on-board instrument which will accompany small robotic vehicles for the exploration of planetary surfaces. The series of Mars missions being promulgated by NASA and ESA from 2001, which start with small planetary rovers and culminate with a
proposed sample-return mission in 2007/8, and with the Mars Express Beagle II Lander mission in 2003 involve Raman spectroscopists who will have the opportunity to participate in perhaps the most-remote sensing Raman experiments yet undertaken, at a minimum distance of about 30 M miles! Along with experiments planned for the International Space Station in 2001/2 involving FTRS and the evaluation of the survivability of living materials to an extremely harsh space environment, it may be stated that Raman spectroscopy is no longer just applicable within the terrestrial realm and will join infrared spectroscopy as a weapon in the armoury of astronomers, exobiologists, and space scientists.

“Per Spectroscopica ad Astra”

ACKNOWLEDGMENTS

The author wishes to record his appreciation to his colleagues in collaboration in some of the international projects cited in this article. In particular, special thanks are due to Professors Fernando Rull, Ole Nielsen, Brian Barry, Jon Russ, Drs Adrian Williams and David Wyn-Williams for their continued support. Also to the funding authorities, ESPRC, NERC, British Antarctic Survey, University of Bradford and the British Council, who made these studies possible.

Raman microscopy and imaging couples the spatial resolution of optical microscopy with the spectral resolution and information content of Raman spectroscopy. Together, a powerful tool for the investigation of chemical, or molecular, heterogeneity is created. Raman microspectroscopy enables the nondestructive analysis of small quantities of sample and the identification of contaminants and inclusions in situ within a matrix—both of great importance and utility in forensic investigations. Perhaps more importantly, it has been recognized that the microheterogeneity of products has an influence on both product performance and appearance. In the analysis of complex, multiphase systems, optical microscopy contrast methods (the majority of which depend upon refractive index changes) are commonly employed to provide information on the structural organization of materials. However, information on the chemical organization of materials is then often based on conjecture. Raman microscopy is arguably the most easily applied of a family of techniques that use the innate spectral signatures of the components as a contrast element and hence provides a method for analyzing chemical heterogeneity in “real” systems.

Typically, the information that would be appropriate from an investigation of chemical heterogeneity would be:

- the number of chemical components present;
- the pure spectrum of each component;
- spatially resolved concentration information for each individual component.

Raman microscopy and imaging provides a tool to determine these important factors in complex, multiphase systems. In its simplest form, the Raman microspectroscopy experiment requires a laser to be focused down to a diffraction-limited spot on a sample and the inelastically scattered light is collected from that point and analyzed. This generates a Raman spectrum, which is indicative of the identity and quantity of the molecular species present in that sample volume. The limiting spatial resolution that can be obtained is of the order of 1 µm in the lateral plane and 2 µm in the axial plane, the microscopes used lending themselves to a confocal optical arrangement that provides this level of depth discrimination.

The information content is constrained to that available in the Raman vibrational spectra and so commonly molecules with distinct functional groups are clearly distinguished, whilst it is more difficult to distinguish specifically between molecules with very similar molecular structure and chemical functionality. It is also a commonly held belief that Raman investigations are hampered by
fluorescence interference, which obscures the Raman spectrum. However, with modern Raman microscopes there are few samples where this limitation becomes completely defeating.

Several approaches to the generation of Raman images (images where the contrast is based on the chemical or molecular heterogeneity) have been established and are discussed in detail. A comparison is made between these different Raman imaging approaches and also with different spectral imaging methods.

1 INTRODUCTION

Why is Raman microscopy such an important development in analytical science?

There are several reasons. In an industrial context, it is because it has been recognized that the microheterogeneity of products has an influence on both product performance and appearance.\(^{(1,2)}\) Hence methods which enable the interrogation of the chemical microheterogeneity in complex, multiphase systems are of great value in understanding how to monitor and influence product properties. Microspectroscopy also enables non-destructive analysis of small quantities of sample and the identification of contaminants and inclusions in situ within a matrix – both of great importance and utility in forensic investigations.

In the analysis of complex, multiphase systems, optical microscopy contrast methods (the majority of which depend upon refractive index changes) are commonly employed to provide information on the structural organization of materials. However, information on the chemical organization of materials is then often based on conjecture.

Whilst there are several approaches to analyzing the chemical heterogeneity of samples, many require the labeling of specific target molecules or the use of phase-specific stains or dyes. However, there is a family of techniques that use the innate spectral signatures of the components and hence provide a method for analyzing “real” systems. Members of this family include vibrational (Raman and infrared (IR)) microspectroscopy and X-ray microscopy as well as optical and fluorescence approaches using innate absorption or fluorescence signals. These approaches preclude the argument about labeling, tagging or staining influencing the system under study. Another crucial argument in their favor over labeling methods is the ability to investigate product microstructure in factory-scale processing. Clearly labeling molecules on such large-scale production is not feasible.

Microspectroscopy can therefore provide chemical information on a point basis and be compared to an optical microscopy image. Typically, the information that would be appropriate from such investigation would be:

- the number of chemical components present;
- the pure spectrum of each component;
- spatially resolved concentration information for each individual component.

The information contained within point microspectroscopy is in principle very powerful and provides not just this desired information but the spectroscopy also contains further molecular information such as alkyl chain conformation. In fact, all of the spectral properties associated with bulk spectroscopic investigations are accessible but now with spatial resolution at a level familiar to optical microscopy, that is on the micrometer scale. Perhaps the most widely applicable and useful member of this family is Raman microscopy and imaging.

It is helpful to define more specifically the methodologies possible within the technique of Raman microscopy and imaging, as there has been some confusion with regard to the terminology. In the USA, and in most of the literature, Raman microspectroscopy has been used to describe the concept of obtaining a Raman spectrum using a microscope as the sampling device. In contrast, European workers have tended to use the term Raman microscopy to describe this experiment. The same confusion is observed in the IR literature. The use of Raman microscopy in this context has created much confusion in neighboring disciplines as the term “microscopy” is generally expected to be applied to the capture and presentation of an image. If the term Raman microspectroscopy is used to describe the simple collection of a spatially resolved point spectrum, then the term Raman microscopy is reserved for the presentation of a true spectral image. Even with this distinction, there is confusion with regard to the way such spectral images are generated, either by mapping or by “wide-field” approaches.

In order to bring greater clarity to the nomenclature, the use of three distinct terms is suggested to describe the various experimental approaches:

1. Microspectroscopy: the use of a microscope as a sampling device to allow spectral information to be obtained from a discrete volume within a sample, preferably registered to some form of conventional optical image. This first approach should strictly not be considered microscopy or imaging as it does not produce an image based upon the spectral contrast but rather uses the microscope as a sampling device for simple point spectroscopy.

2. Mapping and image reconstruction: the use of the microspectroscopy approach coupled to some form
of sample mapping to collect spectral data at many pixels within a sample and subsequently build images based upon the spectral (chemical) heterogeneity.

3. Spectral microscopy: the use of the microscope more conventionally. A wide field of view is imaged using spectral contrast by employing a method of filtering and imaging the entire illuminated area at a particular wavelength or set of wavelengths.

The relative merits of the three approaches are discussed in more detail in section 2.3.

A fourth term, spectral imaging, can then be used to include both experimental approaches of mapping and image reconstruction and spectral microscopy, and this term describes the ability to generate images of the sample where the contrast in the image is derived from the chemical (molecular) heterogeneity. Both experimental approaches result in a spectral image data set that describes the spatial variation of the spectral characteristics of the sample. This provides an excellent representation of the chemical components in a sample and their distribution in a complex, multicomponent, multiphase system. From this data set, an understanding of the molecular interactions or the effects of the molecular distribution on product characteristics can be drawn.

### 2 THE THEORY OF SPECTRAL IMAGING

It is the aim of spectral imaging to produce images which describe the spatial distribution (and sometimes properties) of molecular species in a sample. The information content and data structure within a spectral image data set are complex and the richness of information even in a single spectral image is quite remarkable. This section describes the generic nature of spectral image data and then turns to specific considerations with respect to Raman microscopy.

#### 2.1 Generic Spectral Image Data

The nature of spectral imaging is complex and the richness of the data obtained is quite staggering.

In an xy image plane of a sample, spectral imaging data is actually four-dimensional, each data point having (x,y) coordinates describing its spatial position and wavenumber (or wavelength) and intensity values describing its spectral nature. It is, however, more common to describe spectral imaging only in terms of the spatial dimensionality of the data and consider the spectral dimensions in a different way, so an xy spectral image is commonly referred to as a two-dimensional data set. Clearly visualizing, analyzing and interpreting a data set which is four-dimensional in nature requires the use of sophisticated software tools and these are referred to in more detail in section 6.

Spectral images that include full volumetric xyz images have been obtained and in a similar way these are conventionally referred to as three-dimensional spectral images. These data sets, which are five-dimensional in nature, create even more challenges for the analysis and visualization of the information contained within them.

Figure 1 shows schematically the nature of spectral image data, as they are collected by either mapping and image reconstruction or by spectral microscopy. It should be stressed that communication of spectral image information is much easier if a more familiar optical microscopy image is obtained to which the spectral information is registered, as shown in Figure 1. This also aids interpretation of the spectral image data.

If we consider a two-dimensional (xy) spectral image then the spectral dimensions of the data can be considered in two ways:

1. At each pixel within the xy plane a complete spectrum (intensity vs wavenumber or wavelength) is available – spatially resolved spectral information. This representation is more familiar to spectroscopists and also represents the way the data are collected in a point mapping and image reconstruction approach to the generation of a spectral image data set.

2. Alternatively, a spectral image data set can be thought of as a stack of cards, where each card represents an image based on the contrast (intensity) of the spectral signal at each pixel at a particular wavenumber or wavelength – spectrally resolved spatial information. This representation is more familiar to microscopists and also represents the way the data are collected in a spectral microscopy approach to the generation of a spectral image data set.

With either method of data collection or either method of conceiving the spectral dimensionality of the data, the information is equivalent if the field of view, spectral resolution, spectral range, spatial resolution and image fidelity (number of pixels or pixel density) are identical.

However, it is rare that you would choose to analyze a particular sample by both approaches. The relative merits of the two approaches for collecting spectral image data are discussed in section 3.4.

#### 2.2 Raman Microspectroscopy and Imaging

From the first developments of Raman microprobes in the 1970s it has taken more than 20 years for Raman microspectroscopy and Raman imaging to emerge as a
key analytical technique. The pace has not been set by the theoretical limitations of the technique but rather by the pace of technology development.

The theoretical support for the development of Raman microspectroscopy and Raman imaging has always been very strong. The technique benefits from several key advantages when it comes to understanding heterogeneity in complex, multicomponent samples. These include:

- Innate signals – the Raman effect is inherent to the molecules and provides molecular contrast.
- Ease of sample preparation – sampling is simple, requiring little or no sample preparation, when the conventional microscope backscattering geometry is used. Sampling is further enhanced by the fact that water is a weak Raman scatterer and does not interfere appreciably with the spectra of solutes. Hence biological samples and water-rich product systems lend themselves readily to analysis by this method.
- Spatial resolution – Raman microscopy when operating at the common wavelengths of 780 nm or below, and in a confocal configuration, provides limiting practical spatial resolution of the order of 1 µm in the $xy$-plane and 2 µm in the $z$-direction.

This is comparable with the optical resolution familiar to optical microscopists and so the spectral information is readily referenced to an optical image.
- Spectroscopy on a micrometer scale – all of the theory and literature in support of conventional spectroscopy can now be performed at a spatial resolution of 1 µm. The information content in the spectroscopy is not solely limited to intensity but other spectral signatures can be determined with spatial resolution. Examples include the nature of hydrocarbon chain packing and polymer crystallinity and the identification of different polymorphs of the same compound.
- Ability to deal with complex mixtures – the Raman spectrum is a high contrast signal. Therefore, complex mixtures with multiple chemical components can be successfully interrogated with a single experiment. The ability to both discriminate between small differences in molecules (and hence the spectroscopy) and to pick up the presence of molecules at low bulk concentrations is enhanced in a spectral image data set. This is due to the likely spatial variation in the spectral signatures, which provides a second contrast element in the data set. This enables subtle variations in spectroscopy

---

**Figure 1** Spectral image data sets.
to be determined. Similarly the likelihood is that materials at low bulk concentrations may be locally at high concentration and hence observable. Both of these advantages are enhanced by the use of sophisticated data analysis tools, which essentially co-add and average the entire data set rather than rely upon the information from a single pixel spectrum.

- Quantitation of the signal – the intensity of Raman scattering is directly proportional to the concentration of scattering species; this is clearly of benefit to quantitative studies. Relative quantitation between species is certainly possible but absolute quantitation requires calibration. The commonly presented distribution maps or images of chemical species based upon intensity should be considered to be equivalent to an arbitrary concentration scale unless much effort is made to quantify the response.

2.3 Methodologies within Raman Microscopy and Imaging

The three distinct approaches within the field of Raman microscopy and imaging given in the Introduction are now discussed in greater detail.

2.3.1 Point Microspectroscopy

In this case, the microscope is used as an optical device to enable microprobe sampling. The spectral information is obtained from a microenvironment, without contribution from the surrounding media (Figure 2).

This is the simplest application of the coupling of Raman with microscope optics. The output is a spectrum, preferably with an optical image which shows the point from where the spectral information was obtained.

![Optical image](image1.png)

**Figure 2** Point microspectroscopy is used to obtain spatially resolved spectral information.

This first approach is often referred to as Raman microscopy. However, the author prefers the term Raman microspectroscopy as strictly this methodology does not produce an image based upon the spectral contrast but rather uses the microscope as a sampling device for the point spectroscopy.

2.3.2 Point Mapping

By scanning an area of the sample under the microscope using a motorized stage, spatially resolved point microspectroscopic information is collected and organized into a spectral image data set (Figure 3). This information can be used to reconstruct chemical images based, for example, on Raman intensity at a particular wavenumber (and hence the distribution of molecular species). This approach is currently preferred for samples containing weak Raman scatterers with inherently low contrast in the spectral image data.

![Spectral image data set](image2.png)

**Figure 3** Point mapping of a sample area.

2.3.3 Line Mapping

In the line scanning experiment, the laser is arranged to illuminate a line on the sample and this line is then imaged to the entrance slit of the monochromator and the spectra are obtained spatially resolved along the line at different heights on an imaging detector (Figure 4). There are several instrumental approaches to achieving this and these are described in section 3.4.2.

2.3.4 Point and Line Mapping and Image Reconstruction

The point and line mapping approaches to Raman image reconstruction benefit from the maximum flexibility, that is, the spectral data are complete for each point and chemical images can be constructed from these data in any way appropriate to the spectroscopy.

For example, intensity at chosen wavenumber, intensity ratios, band shifts, band half-widths, etc. can be used to produce chemically specific images. The analysis can then follow the same rigorous spectroscopic principles.
Figure 4 Line mapping of a sample area.

one would apply to single spectra, such as background correction for fluorescence and scattering from the sample. Individual point spectra or the complete spectral image data set can be analyzed to produce semiquantitative information and the spectral resolution is limited only by the monochromator.

The disadvantage is the slow rate of data acquisition – for example, using the simple point scanning/two-dimensional mapping approach, 1 min acquisition per point leads to a total of over 40 h being required to produce a 50 × 50 μm spectral image. However the most recent generation of Raman microscopy instruments with higher light efficiency coupled with more sophisticated data analysis has reduced acquisition times for many practical samples down to 0.5 s per point. An image of 50 × 50 μm at 1-μm spatial resolution can therefore now be collected in approximately 2 h (allowing for additional dead time for stage movement and detector read-out which is not yet optimized). An ultimate goal of 30 min or less for such an image is certainly not unreasonable. The spectral image collection time is not then really prohibitive for the analysis of static systems but even at these data collection rates there is clearly limited application for imaging kinetic phenomena using the point mapping approach.

2.3.5 Spectral Microscopy

By defocusing the laser, or some other means of wide-field or “global” illumination, a field of view is exposed to laser irradiation; the image is then captured in the focal plane of the microscope on an imaging detector after some form of spectral discrimination (Figure 5).

The spectral microscopy approach is sometimes referred to as “global illumination” or “true spectral imaging”, in contrast to the mapping and image reconstruction techniques presented above. In principle, either of the approaches – spectral microscopy or spectral mapping and image reconstruction – produce the same spectral image data set if all of the experimental parameters are arranged to be identical. The relative merits of the different approaches are discussed further in section 3.4.

In practice, if the data set is presented as a series of images based upon the spectral contrast, then a classical microscopist would not distinguish between the mapping or “true microscopy” approaches to data collection. (Scanning electron microscopy, for instance, uses a point mapping approach but is conventionally referred to as microscopy and not as a mapping technique.)

3 INSTRUMENTATION

The early 1990s saw significant improvements in the efficiency of every component of Raman instrumentation, taking Raman microscopy out of the academic laboratory and into routine use within mainstream analytical laboratories. It was not long before the potential in Raman imaging was realized.

The hardware for a generic Raman instrument can be classified into five main areas: excitation laser, sampling device, Rayleigh filter, spectral selection and detector. The Raman experiment is then completed by an appropriate analysis method. These components are represented in Figure 6 and the instrumentation described in more detail below.

3.1 Raman Instrument Components

The individual components of a Raman instrument are now described.

3.1.1 Lasers

Owing to the higher efficiency of modern Raman spectrometers the most common excitation sources are
now low power, air-cooled helium–neon (HeNe 633 nm) lasers, typically operating in the 780 nm region. Argon ion or krypton ion lasers are still in use and now tend to be low power and air-cooled in contrast to the situation in the 1970s and 1980s where high power, water-cooled lasers were more typical.

In Raman spectroscopy a common problem is sample fluorescence caused by the excitation of electronic transitions in the sample at the same spectral wavelengths which have been used to obtain Raman spectral information. Sample fluorescence is most noticeable when using visible excitation laser sources (such as the argon ion or HeNe lasers). At these wavelengths, the probability of electronic excitation and subsequent fluorescence is high, particularly in anything but pure samples and, as a consequence, their industrial applications have been limited.

One solution to the fluorescence problem is to move the excitation wavelength to 1064 nm, in the near-infrared (NIR), away from the majority of electronic transitions and hence obtain virtually fluorescence-free Raman spectra. The use of NIR excitation would appear to be the ideal source until the wavelength dependence of the Raman scattering efficiency is considered. The intensity of the scattering is inversely proportional to the fourth power of the exciting wavelength. Therefore any increase in wavelength dramatically decreases the scattering intensity. The effect that this has on the sensitivity of the Raman experiment has been clearly demonstrated. The 1064-nm excitation has been implemented in the context of Fourier transform (FT) Raman and, although ideal for bulk spectroscopy, it does not prove to be a very practical wavelength for Raman microscopy; this is discussed in section 7.3.

The consensus trade-off between fluorescence suppression and Raman efficiency is now the use of diode laser excitation in the 780-nm region. This is due to the availability of convenient, stable and adequate power diode laser sources and the fact that the Raman signal then remains within the detection window of silicon-based charge-coupled device (CCD) detectors.

3.1.2 Sampling Devices

Sampling devices used in a Raman instrument can be classified into two types. The first category is termed macrosampling devices. The types of vessels used for this purpose include liquid/gas cells (high or low temperature), electrochemical vessels, spinning solid sample holders and more recently fiber optic probes. The second category is termed microsampling devices. These include devices where the sampling area is a spot around 1 µm in diameter. The most common microsampling device is a conventional optical microscope and this is described in detail in section 3.3.2.

3.1.3 Rayleigh Filters and Spectral Selection Devices

In traditional instruments in common use up until the late 1980s, double- or triple-pass monochromators were required in order to achieve a reasonable suppression of the Rayleigh scatter at the excitation frequency. The first monochromator was used to filter out the Rayleigh scattered light at the laser wavelength, whilst the second (and third) monochromator was used to provide the spectral dispersion of the scattered light.

Multiple pass monochromators were designed to be used in spectral scanning mode, or single wavelength mode, with point detectors, typically cooled photomultiplier tubes (PMTs). With the advent of multichannel detectors such as intensified diode arrays and subsequently CCD cameras, many multipass monochromators were re-engineered for use with multichannel detectors. However, the inherent optical design for point detection does not match efficiently to a multichannel detection scheme and so the promise of higher efficiency was never fully realized.

A multipass monochromator configuration can still be advantageous for flexibility in multilaser, high resolution laboratories and for investigations very close to the Rayleigh line. However, the consequence of such an arrangement is that the light throughput is extremely low, of the order of $1\%$.

The availability of high efficiency holographic notch and super-notch filters for Rayleigh scattering rejection has now made CCD–single monochromator systems the norm for Raman spectroscopy. Using these filters is simple and highly efficient. The front monochromator of a double monochromator system can be replaced by a holographic filter and a single-pass imaging monochromator optimized for CCD detection is then used to provide the spectral separation. This dramatically improves the light throughput up to a typical 20–25% collection efficiency in single-pass monochromator–microscope sampling systems, whilst allowing a frequency cut-off near the laser line $(50–100 \text{ cm}^{-1})$. Without excessive attenuation at other wavelengths.
3.1.4 Monochromator Design

As discussed above, the initial use of CCD detectors in Raman was hindered by the fact that monochromator design was not aimed towards two-dimensional detectors but at point detectors. As the light gathering efficiency was not matched to a flat field at the detector the true advantage of collecting a spectral range on the CCD, rather than collecting spectra point by point, was not demonstrated.

The new generation of monochromators have been designed so that delivery is optimized to the image plane of the CCD camera and true image quality of the slit is maintained on to the detector. These monochromators are short focal length and can be Czerny–Turner with stigmatism correction, or on-axis stigmatic,(15) both using conventional diffraction gratings. Even more efficient are the new generation of monochromators based on transmission hologram gratings.(16,17) These provide throughput efficiencies of more than 75% and dual hologram technology can provide high spectral resolution and full spectral coverage by projecting two tracks of different regions of the spectrum on to a CCD detector. These represent the best light throughput efficiency available but are less flexible, requiring a new grating for any change in excitation wavelength.

Imaging monochromators also enable multiple source experiments, such as spectral detection of the light from several fiber optics lined up on the slit or the line scanning imaging facility possible on microprobes(18) which is described in detail in section 3.4. The spatially resolved spectra are obtained using the CCD read-out characteristics to independently read each spectrum at different heights on the CCD chip.

3.1.5 Spectral Microscopy–Imaging Filters

There are several approaches to image filter technologies which have been used in spectral microscopy. As this hardware is specific to the microscopy approach it is discussed in section 3.4.4.

3.1.6 Detectors

For many years PMTs were the only detectors used for measurements with scanning Raman spectrometers. The development of CCD cameras provided an ideal detector for Raman dispersive instrumentation because of their much higher quantum efficiency and the advantage that can be obtained from the two-dimensional character of the detector area. The dispersed spectrum can be projected on to the CCD detection chip and spectral information at a wide range of wavelengths can be obtained simultaneously. The resolution is related to the pixel size on the detector and the degree of dispersion caused by the grating. CCD design formats have been optimized for spectral use (such as 1024 × 256 pixel chips) with the long CCD axis oriented in the spectral direction. More flexible binning and software drivers have been developed specifically for spectroscopic rather than imaging use.

Early CCDs suffered from poor response in the NIR, limiting their use with 780-nm excitation, however back-thinned, deep depletion CCDs with higher quantum efficiencies in the red region of the spectrum are now available.

3.1.7 Advantages of Charge-coupled Device Detectors

As well as the obvious advantage of higher quantum efficiency, there are other advantages of the use of CCDs.

The CCD camera is intrinsically a multichannel device and hence provides a multiplex advantage over using a point detector and spectral scanning. The multiplex advantage is the ability of the system to detect multiple wavelengths instantaneously. A crucial issue is whether there is any multiplex advantage to be gained in Raman spectroscopy.(19) The commonly accepted multiplex advantages are only observed when the experiment is detector noise limited. Raman experiments using CCD detectors often fall into the shot noise limited category, simply due to the low noise characteristics of cooled CCDs, where statistically there is no apparent advantage from using a multiplex technique.

However, there are other factors to consider. The CCD detector removes the requirement for scanning monochromators, naturally increasing the speed of data acquisition through decreased dead time. CCDs have far higher quantum efficiencies than PMT detectors and the noise levels of PMT detectors are higher, which can make equivalent experiments, which are shot noise limited when using a CCD, detector noise limited with PMT detection.

Other advantages are that source power fluctuation (leading to problems with quantitative analysis) are simultaneously observed across the whole spectral range. In CCD systems the fluctuations can average out over long exposure times, which is not possible with single point detectors. By removing the scanning monochromator system, multichannel detection removes drive position uncertainties, which can degrade signal averaging performance and resolves the usual errors of ordinate axis uncertainty in a set of experiments.

3.2 Other Instrument Considerations

Some other considerations should be mentioned with regard to the practical use of Raman instrumentation.
3.2.1 Wavenumber Accuracy

In a dispersive system, the limits on wavenumber accuracy are again related to the optical design, reproducibility of sampling and grating position. Sampling is more easily controlled if a microscope is used as the collection/delivery optics. The grating position reproducibility with CCD–multiplex systems where the grating is held stationary, rather than scanning systems where the grating is moved, is also improved. With appropriate choice of conditions it may not be necessary for the optics to move during a full series of experiments.

Newer monochromator designs such as those based on dual holographic transmission gratings allow for wide spectral coverage at high resolution and negate the need for any moving parts in the monochromator and detection system. Such systems are inherently more stable. Nevertheless it is sensible to calibrate the ordinate axis at appropriate intervals and correct if necessary.

3.2.2 Instrument Response

The development of calibrated white-light sources in Fourier transform Raman spectroscopy (FTRS) to correct for the single beam nature of Raman spectroscopy translates equally importantly to all Raman experiments.\(^{(20)}\) Indeed it is perhaps even more critical in dispersive systems if one is changing, for example, gratings and wishes to make comparisons between spectra obtained on the same instrument but with markedly different throughput characteristics. Such calibration systems for microscope devices using National Institute of Standards and Technology traceable standards are now available commercially and it is strongly recommended that these procedures are followed.

3.2.3 Instrument Software

In the past software to manipulate Raman spectra has been basic. The increase in use of off-line analysis packages, such as GRAMS\(^{\text{TM}}\), and the improving opportunities to convert between file formats make this much less of a consideration. The ease of data acquisition/instrument control is now the major consideration in this area rather than post-collection analysis. However, the analysis of spectral image data sets poses unique problems and is returned to in section 6.

3.3 Instrumentation for Raman Microspectroscopy

In order to obtain an acceptable signal-to-noise ratio (S/N) in a Raman microscope experiment with scanning multipass spectrometers and PMTs, the Raman signal must be integrated for a long time. Therefore, the sample has to withstand a high level of laser irradiation and during these long exposure times the material can suffer from thermal damage or photodegradation. As a consequence, Raman microscopy was of limited applicability until the overall efficiency of Raman spectrometers improved.

The first improvements began to occur in the late 1980s and continued through the early 1990s. Almost every aspect of the Raman instrument’s efficiency improved to make not just Raman microspectroscopy but also the Raman mapping and Raman microscopy experiments a practical reality.

There is now a general consensus on Raman microscopy instrumentation for the microspectroscopy and mapping and image reconstruction approaches. The elements of the instrumentation are now described.

3.3.1 Lasers

The major advance has been the development of small, wavelength stabilized, diode lasers in the region of 780 nm. This excitation wavelength proves to be a good compromise between fluorescence suppression and Raman scattering efficiency and the full spectral shift range remains within the CCD detection window. Generally, the combined improvements in the rest of the Raman instrument imply that small, air-cooled lasers such as HeNe lasers at 633 nm can also be used if visible excitation is desired.

3.3.2 Sampling Device – the Microscope

One of the advantages of Raman microscopy is that a conventional optical microscope can be used as the sampling device; an attachment that allows for entry of the laser beam along the optical axis of the microscope and collection of the backscattered light to be returned to the spectrometer has to be added but, to all intents and purposes, the microscope can be arranged to perform as if it were a conventional optical microscope. This allows for images of the sample to be obtained using the array of contrast mechanisms familiar to optical microscopists and the Raman image information is then registered to this. This can be a great advantage when attempting to fully characterize a heterogeneous sample.

In all cases, the laser excitation and Raman scatter is collected through a confocal arrangement to reject out-of-focus light. This has the advantages of minimizing stray light or fluorescence from other parts of the sample not in focus and providing the optimum spatial resolution in both \(xy\) - and \(z\)-directions. Most systems use confocal pinholes although one commercial system achieves confocality by having the entrance slit of the spectrometer at the confocal image plane (which provides discrimination in one spatial direction) and then narrowing the binning/read-out region on the
